In India, the earliest trepanations are known from Neolithic Burzahom ca. 4300 BP and Harappa, whereas their last occurrence is seen in a 2,000-year-old Iron Age megalithic skull at Maski in Karnataka (Sarkar, 1972). However, there is general lack of evidence of trepanation in ancient India, probably due to the practice of cremation of the dead which was widespread right from Vedic times, and the evidence, if it ever was present, is lost forever. Moreover, the non-tribal mainstream or semi-urbanized ancient Indians also had access to the advance Ayurvedic surgery which the tribal populations did not. This is the reason that trepanation remained in vogue in many isolated tribal groups of the world as mentioned above who stay away from mainstream civilization and follow their traditional beliefs and practices.

Trepanation Methods

In prehistoric times, the flint or obsidian blades were used for such a purpose. Later, copper then iron scalpels were developed. The skill of the surgeon was necessary for the survival of the patient during this awesome operation that involved cutting off the skin and flapping of the scalp and exposing the brain *dura mater*. The ancient surgeons decided on the equipment and methods according to each case, which varied from scraping, gouging, sawing to drilling, and also combinations of these. A canoe-shaped rectangular depression is seen in Peruvian, French, and Palestinian sites (Brothwell, 1994). The Inca in Peru made “grit-like” or reticulated trephinations for healing cephalalgias, abscesses, tumors, or mental illnesses by “crosscut sawing” techniques identified there in 1936; it is rarely found in the Old World (Brothwell, 1994). There are instances where this technique was applied on living patients, in Troy VI Ikiz Tepe and in Lidar Höyük in Turkey (Erdal and Erdal, 2010), and on patient who survived several years. Other similar cases come from Palestine, at Tell Duweir operated by the crosscut sawing technique. The “scraping-cum-incision technique” was applied in some cases on Bohemian skulls. Another technique called “linear cutting” was common in the central highlands of Peru.

Trepanation for Medical Reasons

Many scholars, notably Ullrich (1971), Anda (1951), Verano (2003), Ortner and Putschar (1985), and Bereczki and Marcsik (2005), observed that most of the trephinations in Neolithic and Bronze Age Germany were used for treating and had pathology followed by cranial and postcranial trauma. The patients felt relieved after the bone splinters were removed and the wounds were healed. Other indications for trephination were osteomyelitis, osteitis, periostitis, convulsions, melancholia, epilepsy, paralysis, tumors such as osteomata, cancer metastasis, myeloma, osteosarcoma, meningioma,

echinococcosis, Hand-Schüller-Christian illness, eosinophilic granuloma, lymphogranulomatose, and cerebral abscesses. Certain troubles in the spine and skeletal parts were also treated by trephination, including neurological disorders and mental retardation. Trephinations were also done in certain acquired disorders, metabolic and endocrine malfunctions, tumors, tuberculosis, syphilis, infections, neoplasm, and cysts (Comşa & Sankhyani, 2014).

Large trepanning holes were made in cases of fracture or trauma and the trepanned area was protected in various ways. The Inca, for instance, employed tree bark, golden plaques, or bone fragments. In Melanesia, the cut was covered with banana skin, coconut, or tree bark. The cranial vault bone is not elastic so its healing is not easy and depends more on the metabolic condition, environment, and age of the patient. Therefore trepanation intervention was carried out upon an individual in full health, by a skillful person. The regeneration layer results from conjunctive tissue and not from bone. But, gradually, the bone edges get rounded and eventually fuse together covering the wound.

Magico-religious Trepanations

Scholars have reported many cases where trepanations were also done for the bony roundels or bone disks or roundels to serve as amulets to ward off evil spirits. They were taken from an individual in order to take over the spiritual powers of a dead person as a trophy or amulet. The ancient people wore amulets made of human skulls or other bones believing they transferred the spiritual powers of the dead to them and could protect them against evil spirits. Trepanations for roundels were usually performed postmortem. The roundels appear to have played a significant role in ancient times. The interpretations of the archaic communities around the world were mostly connected with the unknown forces of nature, and this is why the magical-religious practices were very important for those people. Another argument is the fact that, although the

cutting off of such a bone roundel was an act that demanded a lot of care and precision, the amulet had to meet certain criteria. Since the ancient people were mostly practical, we do not see any reason they would have made such amulets or trophies of human skulls or pieces, unless they were considered to be highly important.

In Eastern and Central Europe, we have some good examples of such roundels, from Raklo in Bulgaria or from sites like Nynice, near Plzeň (Hallstatt); Prosmyky, near Lovosice; Tuchoměřice, near Prague (La Tene) in the Czech Republic; or Kunzig-Ost in Germany (Comşa & Sankhyan, 2014). Modern astrologers still suggest that people wear precious stones to gain magic and healing properties.

Pseudo-trephinations

These are sometimes confused with simple holes of different dimensions formed due to physiological, metabolic, and endocrine malfunctions, tumors, infections, syphilis, cultural mutilations, or taphonomic agents, formed antemortem or postmortem (Comşa & Sankhyan, 2014).

Trepanations in India

Roy Chowdhury (1973) opined that trepanation was done on two Bronze Age Harappan skulls from Cemetery R37, namely, Nos. H 802/B and H 796/B. He, without specification, also regarded the presence of trepanation on one Kalibangan skull – at a Harappan site. Sarkar (1972) mentioned that trepanations were also done around 2,000 years ago in the Iron Age megalithic skull (M30) from Maski in Karnataka, South India. He explained that the two circular holes of 22 and 15 mm, respectively, on the either side of the sagittal suture of the vertex (the top of the head) are indicative of trepanation. He also attributed a squarish hole on the right temporal skull of a child of 9–10 years from Lothal, another Harappan site in western India. Sankhyan and Weber (2001) and Sankhyan and Robbins Schug (2011), however, confirmed and described two true surgical trepanations, multiple on a Neolithic Burzahom skull (SKL 7, BZH-3) from the Kashmir Valley (ca. 4300 BP) and one on a Harappan skull, No. H796/B. However, other cases of the claimed trepanations are needed to be confirmed by X-rays or scanning (Fig. 1).

Surgery in Ancient India,

Trepanated Harappan (Left) & Burzahom (Right) Skulls in Palaeoanthropology Laboratory of the AnSI Kolkata

Harappan Trepanation

The Harappan trepanned skull (H 796/B) comes from cemetery in Square R37 located on slightly raised ground to the south of the preserved fractional burial with the head turned on the cheek and the skeleton of burial oriented in N–S direction. All the three skulls, Nos. 796, 796A, and 796/B, form one burial (Gupta, Dutta, & Basu, 1962).

The Trepanned Harappan Skull

The authors of *Memoir No. 9* (Gupta et al., 1962) have studied the Harappan skulls and correctly allocated the No. 796/B to a 25–30-year-old adult male in sub-mesocranic category with the LBI = 75.84, who had a cranial capacity of 1336.67 cc. But, they have made no mention of any cranial trauma and trepanation done on it or other skulls. Therefore, except for Roy Chowdhury's (1973) preliminary mention but without any image, it was not until 2011 that I made the first illustrated highlight of the trepanation at Harappa in the journal *Current Science* (Sankhyan & Robbins Schug, 2012) with a few passing remarks.

The trepanated Harappan skull possesses two depression fractures on the right parietal close

together, as if fused by healing. A fracture superior to and running parallel with the temporal line caused plastic deformation and upheaval of the bone from the coronal suture to the parietal eminence. A second fracture runs perpendicular to the first, from the sagittal to the squamous suture. This fracture caused a linear depression with cracked margins visible on the parietals probably resulting from a severe blow using a strong wooden club. The trepanation was obviously carried out to remove the bone splinters and blood clotting or hematoma and clean the wound as a surgical operation. Whether the man survived the operation may be debated, and the senior author in Robbins Schug et al. (2012) desires computed tomography for confirmation of sclerosis.

However, even further examinations (Fig. 2a) under 20× magnifications show that a thin membranous growth is still visible on the inner margins of the trepanated circular hole despite the preservative coat applied on the skull by the excavators or later workers. Mishandling at the time of excavation (the first reporters were ignorant of the presence of trepanation) and later by many workers, the delicate rejuvenated part might have been damaged and lost. Hence, now we may not expect a prominent evidence of sclerosis even through scanning. Nevertheless, the

Surgery in Ancient India, Fig. 2 (a) Enlarged view of the trepanned hole in Harappan skull H796/B. (b) Trepanned Burzahom skull SKL 7 showing trepanation process

trauma stands as unequivocal cause and witness of a surgical operation done on this skull.

Burzahom Trepanation

The Site and Burial

Burzahom is in the heart of Srinagar City in the Kashmir Valley which is a cup-shaped Himalayan valley surrounded by high mountains. The site was excavated during 1961 and 1968, which yielded ten human skeletons of different cultural stages: Neolithic, Neolithic–Megalithic, and early historic cultures. It is the Neolithic Phase II which has yielded seven human skeletons in the burials, and the trepanated skull (SKL7, BZH-3) is one of them, dated between 4300 and 4000 BP. The burial of the skull had animal bones, antler, horn pieces, and a circular soapstone disk associated with it. The skeleton was in its primary articulation and found in a crouching position, oriented NE–SW and at a depth of 7 ft 4 in. (2.24 m) from the surface level (Basu & Pal, 1980). The skull was reportedly covered with red ochre. The trepanned side of the skull was lying upward, facing the surface.

The Trepanned Skull

The trepanned skull is of a female aged 26–30 years and hyperdolichocranic (very long head), with a long nose and greater calvarial (skullcap) height; the face is narrow and the cranial volume is 1,353 cc, with good dental condition and medium tall stature at 159.1 cm. The forehead is low and slightly receding, with a distinct postglabellar (the space between the eyebrows) depression. Greater affinity is shown with the mature Harappan from Cemetery R37) as well as the modern Punjabi people of northwest India. The cranium shows left-sided swelling or exaggeration/hypertrophy.

Trepanation Process

The Burzahom trepanation was first noticed by Allchin and Allchin (1968) but ascertained by Roy Chowdhury (1973) for medical reasons. However, Basu and Pal (1980), who studied the skeletal features, accepted the presence of

trepanation but considered it a purely postmortem attempt for extracting the roundels as votives/amulets for magico-religious purposes and not for medical reasons. My detailed examination of the original skull, however, leads me to conclude that the trepanation on the Burzahom skull was done for medical reasons.

Although the skull shows multiple trepanations, I think the reason for trepanation was a head injury since the vault is fractured, having a clear fracture line connecting the three larger trepanned holes. In all, there are 11 attempts at trepanation probably done in different stages. The shallow and elongated depressions where only the outer table of the bone is removed probably were for the initial treatment of the patient, and then three actual trepanned holes were made for bloodletting, apparently in a triangular fashion to cover the maximum area to remove the blood. The patient could have not survived since there is no clear evidence of healing of the bone (osteogenesis and sclerosis) visible inside or outside the punctured holes. Roy Chowdhury, however, believed that there is evidence of a ring of sclerosis (callous) around one hole but did not specify the hole. Basu and Pal (1980) also did not recognize any evidence of sclerosis and came to the conclusion that it was not a surgical operation either performed while alive or after death.

I recently reviewed the earlier study and reclassified the 11 perforations into five depressions (1–5) and six trepanned holes (6–11). In the first sitting, the surgeon started his treatment of the patient with a gentle stroke given on the top of the head with a view to see if the patient could be relieved of the pain and chronic ailment and return to normal. This stroke caused a small depression (1) on the top of the cranium. With the same intention, the surgeon gave the second stroke but this time down below on the left parietal bone (2). The third stroke was tried on the posterior extreme (3). All the three strokes were probably given in a single sitting after brief intervals, which resulted in three impressions or shallow depressions (2–3) on the cranial vault. In the second sitting, when the patient could not get any relief from the earlier treatment, the surgeon gave two greater strokes on another site which caused

deeper depressions (4 and 5), followed by another and bigger one that removed the outer table of the bone into the diploe space by perforating the skull slightly but leaving the inner table intact (6). Again, when the patient showed no sign of relief, the surgeon thought of real deeper interventions in the third sitting, which perforated the cranium and formed two complete holes (7 and 8) made close by possibly for bloodletting and taking out the degenerated blood tissue. They are almost of the same size and outline and were made very neatly and carefully made by the same instrument. Finding no relief to the patient, the surgeon made another trepanation in the fourth sitting, which was probably his last effort on the living patient when a single neat rounded hole (9) was made. However, the patient perhaps succumbed to death in this attempt, so that the remaining two holes (10 and 11), which are bigger in size and uneven in shape, were most likely a postmortem study trial to ascertain the cause of the pathology and for a simple demonstration/training to a future surgeon. There are fracture lines emanating from these big perforations indicating that the patient had suffered from a trauma. Because she had no cure, she might have turned insane or epileptic and wandered here and there and likely fell down and got the head injury evident from the cranial trauma. This trepanation was therefore necessitated for surgical reasons to treat the injury.

No special instruments that could have been used in trepanation were found in the trepanated burial site except some animal bones, antler, horn pieces, and a soapstone circular disk. It is possible that the antler piece or animal bones could have been used as drills of various diameters for trepanation. Erdal and Erdal (2010) observed that only the drilling technique with flint or bone drills was practiced during Neolithic times, whereas the cutting and scraping techniques were developed later with bronze instruments during the Bronze Age, followed by iron instruments during the megalithic period. With this background, although trepanation is the job of a specialist, the possibility of a Bronze Age Indus surgeon speculated by George Weber earlier (Sankhyān & Weber, 2001) seems unlikely.

I concur with Basu and Pal (1980) about the extraction of the roundels from the Burzahom skull except in the postmortem trepanation. I consider it less likely that the Burzahom skull was intended for extracting roundels which are possible through a cutting technique and not by the drilling evident at Burzahom. The drill would rather damage the bone and push that inside the skull making the piece irretrievable. Human skulls and bones are used by sorcerers and magico-religious experts in spiritualistic treatments, yet there is no direct evidence to support the idea that the Burzahom trepanation was intended for extracting roundels as votives. There could have been spiritualistic treatments of the patients, but trepanations were attempted with a surgical motive, even though the patient could not survive the procedure. The retrieval of cranial roundels could only be the last thought after the postmortem operation but lacks evidence.

Who Was the Burzahom Surgeon?

If it was a case of surgical operation, then who performed the surgery is the mind-boggling question. In this quest, I recently re-scrutinized the craniometric data of 10 skeletons and noticed homogeneity, except the cranium of skeleton 6, which stood at a contrast. Although (Basu and Pal, 1980) had diluted its significance by attributing the differences to individual variation within a community and not due to any migration to Burzahom, I believe that he could have been the man brought to the community as a medical and spiritual healer – a shaman. He was a very robust man of an age between 51 and 55 years. His skull is mesocranic (round or as broad as long) with LBI (74.9) and receding and low forehead (frontal). His face was very broad with large bizygomatic diameter (150 mm) and the nose also similarly very broad (hyperchamaerrhine, nasal index 68.0). All these features made him a person of phenotypically very distinct population since all other skeletons of Burzahom collection are of long-headed (dolichocranic) to very long-headed (hyperdolichocranic) people with long and narrow faces and longer noses. Burzahom men were also taller (SKL 1 = 176.4 cm,

SKL 9 = 178.5, SKL 10–177.1 SKL) than the “robust” man (173.4 cm). There is great paucity of comparative data, but the craniometric data table of Basu and Pal (1980) lists one such very similar skull (NGK 7) in contemporary Neolithic Nagarjunakonda (Andhra Pradesh). How could he have come from such a distant place as South India to Kashmir? Either the seminomadic people of Burzahom had some information about this man or he was a crazy tourist who walked over to visit the Himalayan paradisaical Kashmir Valley. He was accepted by the Burzahom community for the treatment of their young women, first spiritually and then medically and finally surgically. For his acts of kindness, he was allowed to stay with others, and the valley attracted him to spend his life there. So he was buried in their settlement.

Surveying

Frank J. Swetz

Surveying is the mathematical science that incorporates the application of geometric principles with concepts of measurement in order to delineate the forms, position, and extent of terrestrial features or man-made structures. It is an ancient activity that has been used by all urbanized societies. The establishment and maintenance of land boundaries, the construction of walls, and the lay out of irrigation systems and aqueducts rely on the use of some kind of surveying. Extent structures such as Stonehenge in England, the Great Wall of China, Machu Picchu in the Andes of Peru, the Great Pyramids of Giza, or the temples of Angkor in Cambodia testify to their builders' knowledge and use of surveying. However, all too often, in the ancient world, surveying activities were the closely guarded prerogative of an elite, members of a priestly or bureaucratic class. Knowledge of their mathematical discipline was usually transmitted orally from master to student. Such practices, combined with the ravishes of time, account for few existing documented records of old surveying practices and techniques. Therefore, much of what can be gleaned about surveying in early non-Western societies is speculative in nature and rests on extant archaeological and architectural evidence.

The most basic of surveying activities include the determination of straight horizontal and vertical lines and the establishment of a level plane

upon which structures can be erected or reference slopes established. Instruments to achieve these goals are strikingly simple: straight horizontal lines can be obtained through the use of sighting poles or stakes and retained by the use of stretched cords or ropes; straight vertical lines are obtained by the use of a plumb bob, a weight suspended from a string, and a level plane can be constructed with the assistance of a leveling device such as a water-filled trench.

Rope Stretching

Herodotus (ca. 484–425 BCE), the Greek historian, attributed the origins of geometry to the Nile Valley of Egypt, where priest-surveyors stretched ropes to mark out land boundaries. These “rope-stretchers,” or as Herodotus called them *harpedonaptae*, are the first historically recognized surveyors. Rope stretching activities also took place in Babylonia where ancient clay tablets mention the act of “stretching a field,” that is using a rope to determine the dimensions of an agricultural field and denoting a particular individual as “the dragger of the rope,” a surveyor. It appears that these early Egyptian and Babylonian land measuring activities were prompted by the need for royal levies. However, in the early Indus Valley civilization, rope stretching served another need. The *Śulbasūtras* (Rules of the Cord), compiled between the fifth to eighth centuries BCE, supply geometric prescriptions for the construction of ritual altars. These prescriptions were based on rope-stretching and were carried out by the Vedic priests. Later Pali literature makes mention of “rope holders” (surveyors) in reference to land measurements. In all early urbanized societies, rope stretching provided the basis for surveying.

Egypt

Surveying activities in Egypt certainly preceded the fifth century BCE observations of Herodotus. An inscription on the Palermo Stone dating from

the Old Kingdom period of Egyptian history (ca. 3000 BCE) notes the existence of land surveys. Tomb inscriptions of about the same period mention the existence of land registry offices. A wall scene in the tomb of Menna at Thebes depicts surveyors at work. The scene shows two men measuring a field of corn with a long cord on which knots are marked at intervals of about 4 or 5 cubits. A standard measuring cord or rope of this period was 100 cubits (52.5 m) long. To obtain accurate vertical lines as well as to sight over long distances, Egyptian surveyors use the *merkhet*. This instrument also existed in Egypt from the earliest times; it consisted of a short plumb-line and plummet hanging from a holder that contained a sighting slit. Thus alignments could be made on distant objects. Merkhets were employed in the orientation of temples in a process called the “stretching of the measuring cord.” Egyptian surveyors also employed two types of levels, the water level via a water filled trench which was suitable for large scale leveling, and the plumb-bob level erected with the aid of a wooden, right isosceles triangular frame work. Modern surveys have affirmed that the ancient Egyptians obtained very accurate results using their simple tools: the foundation for the Great Pyramid of Giza is almost perfectly level; boundary markers on the sides of the Nile River are aligned over long distances and a very accurate system of nilometers (flood gauges), were established along the Nile from its delta to the First Cataract, a marvelous feat of leveling.

Babylonia

Large scale construction projects existed in the Tigris-Euphrates region as early as 2300 BCE. The accomplishments of Gudea of Lagash, an engineer or architect of this time, is commemorated by statues which depict him holding a tablet containing scaled plans for a structure. These plans are superimposed on a rectangular grid. Both the use of scaling and a rectangular reference grid indicate the existence of a high level of surveying skill at this time. Further, extensive systems of irrigation channels relied on the

establishment of adequate gradients or slope determined by leveling techniques. Fragments of Babylonian clay astrolabes dating back to the second millennium BCE have been found. With such instruments, observers of the time could determine angles of inclination; however, it is believed that these astrolabes were employed for astronomical sightings rather than terrestrial surveying.

Ancient India

Archaeological evidence from such sites as Mohenjo-Daro and Harappa, cities of the early Indus civilization (3500–2500 BCE) indicate that city planning principles were followed. Buildings were uniform in appearance, and roads were laid out at right angles to each other. The existence of sewerage systems as well as flowing aqueducts testify to a knowledge and use of leveling principles. Builders of the cities of Mohenjo-Daro and Harappa knew surveying. Linear measuring scales found at excavation sites in the region indicate the early Indus peoples employed a decimal system of measurement. This system was based on a “Mohenjo-Daro inch” of 0.67 cm. Further, at Lothal, the remains of a sighting instrument were found. The instrument consists of a hollow shell with four slits cut into its sides. These slits are situated at right angles to each other and allow for perpendicular sighting as would be necessary in surveying a rectangular road system. During the later *Śulbasūtra* period (800 BCE), ► [bamboo](#) poles, *saṅku*, were used for measuring and laying out circular regions, and a standardized chain or measuring rope, *rajju*, was employed. The *Śulbasūtra* texts describe an extensive mathematics supporting its rope stretching surveying techniques. Included in this mathematics was a theory of similar triangles.

While works of later Indian mathematical authors primarily concerned applications of mathematics to astronomy, some also included mathematical information for surveyors. Āryabhaṭa I (476–550) in his *Āryabhaṭīya* (ca. 499) discusses procedures for finding areas and volumes of plane figures and solids.

► **Brahmagupta** (ca. AD 628) in his *Brahmasphu-tasiddhānta* (Correct Astronomical System of Brahma) provides much information relevant to the needs of surveyors including specific computation procedures necessary for working with a shadow gnomon, a sighting staff employed for inclined sightings, thus incorporating a concept of angle into surveying activities.

China and the Far East

Early Chinese society was river based. Settling along the banks of the Yangtze and Hwang Ho rivers, the Chinese people harnessed and controlled the rivers by a system of dikes, canals, and irrigation channels. These construction projects required a knowledge and use of land surveying. Surveying was openly recognized as an important societal activity; folk hero Fu Xi and legendary emperor-engineer Yu the Great were often depicted holding surveying instruments.

Discussions and illustrations in extant texts and reference works provide some knowledge of the instruments used by early Chinese surveyors.

Calibrated sighting poles, *biao*, were used in conjunction with sighting tubes, *wang tong*, or sighting boards, *ce shi pai*. A water level, *zhun*, was employed for leveling and a bamboo measure tape, *bu che*, devised for chaining land. A primary surveying instrument was the L-shaped set square or gnomon, *ju*. The earliest documented reference to surveying is found in the ► **Zhoubi Suanjing** (The Arithmetical Classic of the Gnomon and the Circular Paths of Heaven, ca. 100 BCE–AD 100) where in a fanciful conversation between Zhou Gong, a duke of the Zhou dynasty (ca. 1030–221 BCE) and the Grand Prefect Shang Gao, the duke advises the Prefect in the use of the set square. More substantial information on the mathematics of surveying is supplied in ► **Jiuzhang suanshu** (The Nine Chapters on the Mathematical Art, ca. 100 BCE). The work contains nine chapters on specific applications of mathematics. Chap. 1, “Field Measurements”; Chap. 5, “Construction Consultations” and Chap. 9 “*Gougu*”(right-triangle) are directly concerned with surveying computations (Fig. 1).

In AD 263, the scholar-official Liu Hui wrote a commentary on the *Jiuzhang* and revised much of

Surveying, Fig. 1 Classical Chinese surveying instruments. (a) *Biao*, calibrated sighting pole; (b) water level, *zhun*; (c) *bu che*, a bamboo measuring tape (From Frank

Swetz, *The Sea Island Mathematical Manual: Surveying and Mathematics in Ancient China*. Penn State University Press, 1992. Used with permission of the author)

its contents. He paid particular attention to the ninth chapter and extended its collection of problems to allow for more surveying situations which involved the obtaining of measurements to inaccessible points. Liu stressed a technique called *chong cha* (double difference) requiring two distinct sighting observations from separate locations. At the beginning of the Tang dynasty (AD 618–906), Liu's problems involving double differences were separated from the *Jiuzhang* and made into an independent mathematical work on surveying, the *Haidao suanjing* (Sea Island Mathematical Manual). In AD 656, the Royal Academy established an official curriculum to be used for the training of state officials. The *Haidao* was included among the ten mathematical works to be studied. Later, this curriculum was adopted in Japan and Korea where the instructions of the *Haidao* provided the basis for surveying. One of the most accomplished feats of early Chinese surveying was begun in the year 724 when the State Astronomical Bureau of the Tang dynasty initiated the first meridian survey in the ancient world. Under the supervision of the scholar Yixing, 13 observation stations were established near the meridian 114°E and between latitudes 29°N and 52°N. Observations were taken over a period of several years. The expedition determined the angular attitude of the north celestial pole above the horizon and recorded the length of shadows at noon for the summer and winter solstices and equinoxes.

The *Haidao suanjing*'s problems became the basis of later works which considered surveying computations. In 1247, the mathematician ► [Qin Jiushao](#) published ► [Shushu jiuzhang](#) (Mathematical Treatise in Nine Sections). Three of its nine chapters concerned survey applications: Chap. 4 was entitled "Surveying"; Chap. 7, "Architecture"; and Chap. 8, "Military Matters" which concerned the use of surveying techniques for observing an enemy from a distance. His contemporary, ► [Yang Hui](#) wrote *Tian mu bi lei cheng chu jie fa* (Practical Rules of Arithmetic for Surveying). Toward the end of the Ming dynasty, Western influence began to penetrate China. In 1582, the Italian Jesuit Matteo Ricci arrived in Macao and eventually

made his way to Beijing where he used his mathematical and scientific knowledge to win favor with the court. Ricci collaborated with the scholar Xu Guangqi to publish *Celiang fayi* (Essentials of Surveying) (1607–1608). This book introduced contemporary European survey and land measurement methodology to China. Xu himself was a skilled surveyor and wrote an appendix to the *Essentials of Surveying*. It appeared in 1608 under the title *Celiang i tung* (Similarities and Differences [Between Chinese and European] Surveying Techniques). From this period onward, surveying in China combined both European and traditional theories and practices.

The Islamic World

Islam did not emerge as an intellectual and political force until about AD 726 with the establishment of the 'Abbasid Caliphate. From their capital in Baghdad, the early 'Abbasid caliphs patroned the collection of scientific works and used this acquired knowledge to consolidate their religious and political empire. Their era was marked by the building of new canals, bridges and aqueducts and by the reconstruction of old Babylonian irrigation systems. Surveying was used in this work. While Muslims became the heirs of Babylonian, Egyptian and Greek surveying theory, they soon became accomplished practitioners and innovators in their own right. Religious prescriptions required daily prayers toward Mecca; in turn, mosques had to be constructed facing Mecca. Thus determining the *qibla*, or direction of Mecca from a given location, became an important task for surveyors.

Muslim surveyors used several methods of leveling: the plumb-bob level was employed as well as leveling poles. ► [Al-Khāzinī](#) (ca. 840) and Ibn-al- 'Awwām wrote on the use of leveling poles. The latter wrote a handbook for farmers that included the layout of fields. Right angles were laid out with the use of an L-shaped square, *kunija*. Abu'l Wafā (940–998) wrote about the use of such a square. The most complete early Muslim treatise on surveying was written by Muḥammad ibn al-Hassan al-Hasib ► [al-Karājī](#)

(ca. 1000). It was entitled *Kitāb al'ūqūd wa'l abniyah* (Of Vaults and Building). Al-Karajī discussed both the mathematical and practical aspects of surveying and provided specific instructions for the surveying of tunnels and underground aqueducts, ► [qanat](#). Later writer Abū Saqr al-Qabisi introduced trigonometric methods into surveying computations.

The one area of surveying in which Muslim scientists and craftsman excelled was the design and utilization of measuring instruments. Their knowledge of the astrolabe was obtained from the works of Ptolemy. The first noted Muslim maker of astrolabes was al-Fazārī (d. ca. 777) who worked under the patronage of al-Mansur. By the end of the eighth century a number of scholars were producing works on the construction and use of the astrolabe. The most famous of these scholars was Māshā'allāh (762–ca. 815), a Jew who worked under Islamic patronage. His *Kitāb sana'at al-asturlāb wal-'anal bihā* (Book of the Construction of an Astrolabe and Its Use) became the authoritative reference of its time. At a later date (ca. 1380), Chaucer used Māshā'allāh's theories in his European introduction of the astrolabe as a scientific instrument. It was Muslim efforts that resulted in the astrolabe becoming a valued instrument in land surveying activities. Similarly, the Jacob's staff, a popular medieval instrument for determining planar angles, is believed to have reached Europe via Muslim sources and may have had its origins in navigational methods used by early Muslim traders. The oldest actual description of this instrument comes from a navigator's manual, the *Mohit*, written by Sidi al-Chelebri, captain of the Turkish fleet under Sultan Suleimann in 1554.

Pre-Columbian America

Although no written records exist to document the surveying knowledge of early native American civilizations, archaeological sites testify to these peoples' application and understanding of surveying techniques and principles. The city planning and construction carried out by the Olmec, Maya, Teotihuacan, Toltec, and Aztec

peoples of South and Central America indicate that they undertook some surveying activities. For example, the Aztec capital of Tenochtitlan was laid out according to a grid system. It contained markets, palaces and streets and canals and held a population of approximately 200,000 people in the year 1521. Temples and ball courts were oriented to the four cardinal directions. Aqueducts brought fresh water into the city from many miles distant. Some of the Aztec surveying instruments are known by name; plumb line, *temetzlepilolli*; the water level, *atezcath*; set square, *tlanacazanimi*; measuring scale, *tlahuahuanoloni* and the construction compass, *tlayolloanaloni*.

Surveying in Ancient Egypt

Hans Barnard

Cotsen Institute of Archaeology, and NELC,
University of California, Los Angeles, Los
Angeles, CA, USA

The English verb “to survey” refers to a variety of activities, two of which will be discussed here with an emphasis on the way in which these were practiced in Ancient Egypt. The first can be provisionally defined as the techniques to reduce reality to fit onto a map or a model and the second as the techniques to transfer the information and

ideas reflected on a plan or a model to the real world. Up until very recently, a surveyor would go into the field with two instruments, one to measure angles, such as a transit or a theodolite, and one to measure distances, such as a measuring tape or an electronic distance measuring device (EDM). Modern technology has combined these two instruments into one, and they are referred to as a “total station,” which can perform both functions. The underlying principles of surveying, and the fact that these are based on the accurate measurement of angles and distances, were already mostly understood in Ancient Egypt. It must be kept in mind that the Ancient Egyptian civilization lasted for more than 3,000 years and did change slowly but continuously. The technology and methodology of surveying will have been different during the various periods of Egyptian history (Table 1). From the available evidence, it is not possible to determine an exact chronology of the discipline of surveying in Ancient Egypt, and the following discussion will be thematic rather than sequential.

This evidence comprises a number of preserved ancient tools that were likely used for surveying, several plans and maps from various periods, inferences from marks and modern measurements in extant structures, and a few surviving texts on the subject. The Moscow (or Golenishchev) Mathematical Papyrus, probably written during the eleventh dynasty (unknown provenance, now in the Pushkin State Museum of Fine Arts in Moscow), discusses a series of problems of the area and volume of complex shapes, including a curved surface (problem 10) and a truncated pyramid (problem 14). The Rhind (or Ahmes) Mathematical Papyrus, written around 1550 BCE but claiming to be a copy of a twelfth dynasty text (found in Luxor, now in the British Museum in London), deals with a series of problems of area and volume, including the area of a triangle (problems 4 and 51), a rectangle (problems 6 and 49), and a circle (problems 38 and 50) as well as the volume of a cylinder (problems 41 and 43).

Surveying would have been needed in Ancient Egypt, from the Old Kingdom onward, for at least

Surveying in Ancient Egypt, Table 1 The chronology of Ancient Egyptian civilization following Baines and Malek (2000, pp. 36–37)

Period	Dynasties	Date
Early Dynastic Period	1st–3rd Dynasties	2950–2575 BCE
Old Kingdom	4th–8th Dynasties	2575–2150 BCE
First Intermediate Period	9th–11th Dynasties	2125–1975 BCE
Middle Kingdom	11th–14th Dynasties	1975–1640 BCE
Second Intermediate Period	15th–17th Dynasties	1630–1520 BCE
New Kingdom	18th–20th Dynasties	1539–1075 BCE
Third Intermediate Period	21st–25th Dynasties	1075–715 BCE
Late Period	25th–30th Dynasties	715–332 BCE
Greco-Roman period	Macedonian and Roman rulers	332 BCE–395 CE

two important applications. First was the construction of the famous tombs, temples, and pyramids, some of which still stand today and testify to the accuracy of the measurements. Second, and with a larger impact on daily life, were the measurements to restore the outlines of the agricultural fields after the yearly inundation of the Nile in July and August. The maximum height of the inundation, measured in nilometers at several places, differed from year to year and with that the area of arable land. The available land needed to be redistributed each year and taxes were levied accordingly (Shaw and Nicholson, 1995; Harrell, 2001). This is attested in the following remark of the Greek historian Herodotus, who traveled through Egypt in the fifth century BCE.

The King would send men to inspect and measure the loss of cultivated land in order that from then on some of the tax, proportionate to the report of the loss, might be remitted. I attribute the invention of geometry to this cause and from Egypt it spread to Greece. (Herodotus, *History* 2.109, translation Shore, 1987, p. 125)

Measuring distances in Ancient Egypt was done in the same way as it is still mostly done today: by comparing the unknown with a known distance indicated on a tape measure or a ruler. Several ancient measuring rods have been preserved, most of them dating to the New Kingdom or later. Two were found in the tomb of Kha, the architect of the Pharaoh Amenhotep II (Eighteenth Dynasty), in Deir al-Medina (near Luxor) and are now kept by the Museo Egizio in Turin. One was gilded and probably a gift not meant for daily use; the other is hinged and was most likely used by its owner during his work (Arnold, 1991). Longer distances were measured with a rope that had knots at regular distances, an activity known as “stretching the cord” (Shore, 1987). This rope, reminiscent of “Gunter’s chain” used by seventeenth- to nineteenth-century surveyors, is often depicted ending in the ram’s head of the god Khnum, the creator god, indicating the importance attached to the measurements and their accuracy. A depiction of land surveyors in action can be found on the top register of wall 5 in the tomb of Menna, an administrator who lived during the reign of Pharaoh Tuthmosis IV or that of his successor Amenophis III (Eighteenth Dynasty) (Fig. 1).

No single Ancient Egyptian unit of length can be given, as this not only varied over time but also by purpose and place. Several systems existed simultaneously, as they did in Europe until very recently (the Convention of the Metre was signed in 1875 and the International System of Units in 1954, but neither are implemented, or even adopted, by all countries). The basis for the Ancient Egyptian unit of length was the cubit, the length from the elbow to the tip of the middle finger (Arnold, 1991; Gillings, 1982; Skinner, 1954). A cubit was divided into seven “palms” and 28 “fingers” (one palm being four fingers). Two cubits seem to have been in use, the “royal cubit” and the “short cubit”; the former was most often about 524 mm (20.6 in.) and the latter 449 mm (17.7 in.). A finger was therefore either approximately 19 mm (0.74 in.), when taken from the royal cubit, or approximately 16 mm (0.63 in.), when taken from the short cubit (Gillings, 1982). It is possible that at times, the

Surveying in Ancient Egypt, Fig. 1 Fragment of the top register of wall 5 of the 18th Dynasty tomb of Menna, showing land surveyors in action (photograph by Robert

L. Mond and Ernest J. Mackay, 1914–1916, used with the kind permission of the Griffith Institute, Oxford, UK)

Surveying in Ancient Egypt, Table 2 Overview of the most important Ancient Egyptian units of length

	Fingers	Cubits	mm	Square (cubits ²)	Square (mm ²)
Remen	19.5	$1/2 \times \sqrt{2}$	371	$1/2$	137,288
Cubit	28	1	524	1	274,576
Double-remen	39	$\sqrt{2}$	741	2	549,152

short cubit was divided into only six palms and 24 fingers (Skinner, 1954). The royal cubit would then be close to one short cubit plus four fingers (one palm) long. A hundred cubits, 52.4 m (171.9 ft) in length, was called a *hayt*, a *khet*, or, in the Greco-Roman period, a *schoenia*. An area of 100×100 cubits (a square hayr, khet, or schoenia) was called a *setat* or, in the Greco-Roman period, an *arura* (Neugebauer, 1954; Shaw and Nicholson, 1995).

A remarkable additional unit was the *remen*, defined as half the diameter of a square with sides of one royal cubit in length. The length of this diameter is $\sqrt{2}$ cubits, which cannot be written as the sum of reciprocal fractions (such as $\sqrt{2} = 1 + 1/3 + 1/13$, etc.), the notation system used in Ancient Egypt, but only as an unending decimal fraction (like $\sqrt{2} = 1.41421\dots$). A remen would be about 371 mm (14.6 in.) or, by coincidence, almost exactly 19.5 fingers (Table 2). The advantage of the remen was that it allowed areas of land to be halved, or doubled, while preserving the proportions simply by

changing the unit, much like the ISO system for paper sizes. A square with sides of a cubit, for instance, has twice the area of a square with sides of a remen and half the area of a square with sides of two remen (a “double remen”). To calculate the area of a circle, π (pi) was approximated as $(2 \times (1 - 1/9))^2 = 16^2/9^2 = 256/81$, which equals 3.16049... (whereas the correct value of $\pi = 3.14159\dots$ and 355/113 would be a better approximation).

Less is known about how angles, the second basic element of surveying, were understood in Ancient Egypt. There is ample evidence of the use of plumb bobs, often combined with a set square or another device that could have served as a sight, which essentially create a 0° angle with the vertical (and a 90° angle with the horizontal). Some of these instruments were apparently used to establish levels (Arnold, 1991; Lehner, 1997). Marks representing different elevations are preserved in several structures among which are the Fourth Dynasty Mastabet al-Fara’un, the burial complex of Pharaoh Shepseskaf, in Sakkara (near

Cairo), the Fifth Dynasty pyramid of Niuserre in Abusir (near Cairo), and the Eleventh Dynasty temple of Mentuhotep in Deir al-Bahri (near Luxor). It has been suggested that water in channels cut for this purpose was used to create a level plain (Edwards, 1993), which can be considered a 0° angle with the horizontal (and a 90° angle with the vertical).

It is unclear how a right angle on a given base line, essential for many surveying tasks, was constructed. There is no evidence that the special case of the Pythagoras theorem, which proves that a triangle with sides of 3, 4, and 5 units will have one right angle, was employed (Gillings, 1982). Over short distances, a right angle could have been constructed by sighting over a set square (Arnold, 1991; Edwards, 1993). The accuracy of this method could be improved by several techniques, but probably not sufficiently to account for the results evident from the surviving structures. Another way to construct a right angle is by establishing two large equilateral triangles with one side and two corners in common. The diagonals of the resulting rhomboid, one of which would correspond with the base line, will be at a right angle (Arnold, 1991). What techniques were used to achieve the observed level of accuracy with the tools available at the time remains enigmatic, but the ancient surveyors could draw on generations of experience with the layout of agricultural fields and canals.

There is some archaeological and textual evidence about angles other than 0° and 90° , relating to the inclination of pyramids, pylons, and the walls of buildings. This includes a set of preserved marks in the foundation trenches of Old Kingdom mastaba number 17 in Maidum (Arnold, 1991) and problems 56–60 of the Rhind Mathematical Papyrus (Gillings, 1982). The angle of the face of a structure was described using the *seket*, which can be defined as the length of the setback of the building from the vertical at a height of one cubit or, in modern terms, as the cotangent of the angle of the wall with the horizontal (Gillings, 1982). A vertical wall has a *seket* of zero, and a wall with an inclination of 45° has a *seket* of one cubit. The

Great Pyramid in Giza, built by Pharaoh Khufu (Cheops) of the Fourth Dynasty, rises at an angle of $51^\circ 52'$ with the horizon and consequently has a *seket* of 0.79 cubit (about five palms, two fingers). The measurements by the ancient surveyors were sometimes transferred to the structures under construction by elaborate means, such as the mudbrick walls under the outer court of the Twelfth Dynasty pyramid of Senwosret in Lisht, believed to indicate the desired level to which the court had to be built up, or the lines of rock-cut postholes surrounding the Great Pyramid (Arnold, 1991).

Measurements were not only needed to ensure a practical and secure structure but often also to make it correspond to religious beliefs or cultic necessities. Despite a dearth of concrete information, the latter has become subject of much speculation. Many proportions of structures and angles of shafts are assumed to have had a special meaning, but these are rarely fully understood. The orientation of the pyramids according to the cardinal points is generally thought to have been motivated by stellar elements in the Ancient Egyptian religion. This orientation was most likely achieved by astro-surveying, performed by priests rather than surveyors. One instrument that was probably used for this is the *bay*, part of a palm rib with a slit at its base through which stars, or the sun, could be observed. A bay was used in combination with a merkhēt, which doubled as a plumb bob and a sundial. A set of these instruments (now in the Staatliche Museum Charlottenburg in Berlin, found in Abydos?) once belonged to Hor, a priest of the Twenty-Sixth Dynasty. According to the inscription on the merkhēt, it "... knows the motion of the two discs (sun and moon) and every star..." (translation Wells, 1999, p. 37). An inscription on the bay indicates that it is "... for indicating the commencement of a feast..." (translation Wells, 1999, p. 37). With these relatively simple instruments, it is possible to observe, through the slit in the bay, the passing of a star across a vertical line, established by the plumb bob attached to the merkhēt. In the day, the bay would cast a shadow that could be aligned

rather accurately because of the slit in the top. Either could be used to find true north, for instance, by bisecting the angle of the rising and setting of a celestial body over a horizontal plane (Edwards, 1993; Lehner, 1997) or by observing the alignment of a pair of selected stars (Spence, 2000). Surveyors would then again be needed to transfer the observations to the actual building under construction.

Celestial observations were also used for the first known attempt to calculate the circumference of the Earth, by Eratosthenes during the reign of Ptolemy III Euergetes (246–221 BCE). Eratosthenes was born in Cyrene (Libya) and brought to Egypt as a tutor for the son of Ptolemy III and a librarian of the library of Alexandria (with about 500,000 “books”). Alexandria was the capital of Egypt during the Greco-Roman period and, at the time, the most powerful and influential city in the region. Thanks to the patronage of the Ptolemaic rulers and the renowned library, scholarly and scientific knowledge advanced greatly. Basing his calculations on the difference, on the same day, in the height of the sun in Alexandria and in Aswan, Eratosthenes came surprisingly close to the actual figure (Berthon & Robinson, 1991); an achievement that took about 1,500 years to surpass (Neugebauer, 1954).

Sūryasiddhānta

K. V. Sarma
Madras, Tamilnadu, India

The *Sūryasiddhānta* is a complete work on Hindu astronomy and is more popular and widely studied in North India than in the South. In order to enhance its prestige and antiquity, it is stated in the text itself (1.29) that it had been communicated by a representative of the Sun God to Maya, several 1,000 years ago. However, both internal and external evidence shows that the work was composed between AD 600 and 1000. In about 500 verses, distributed through 14 chapters, the work deals with all aspects of Hindu astronomy,

K. V. Sarma: deceased

and also cosmology, geography, astronomical instruments, and time-reckoning. It follows the midnight day-reckoning.

The contents of the work are comprehensive. Chapter I speaks about the circumstances that led to the composition of the work, the aeons and aeonary revolutions of the planets, the principles underlying the computation of the planets and the nodes, the position of the planets at the beginning of the current aeon, the prime meridian and local time, and the inclination of the orbits of the planets. The time units given in the work are more in conformity with the *Purāṇas* than with other texts on Hindu astronomy. Chapter II deals with the computation of the true motion and the true longitudes of the planets. Chapter III is devoted to the determination of the directions, place and time, and also the calculation of the precession of the equinoxes. It is noteworthy that the *Sūryasiddhānta* is the earliest available Indian text which contains a discussion of the calculation of the precession of the equinoxes. Chapters IV and V deal in detail with lunar and solar eclipses and their computation. Chapters VII and VIII are concerned with the conjunction of one planet with another, and a planet with a star, including their observation. Chapter IX deals with the determination of the heliacal rising of the planets and Chap. X with the phases of the moon. Chapter XI is concerned with the phenomenon of *pāta*. Cosmology and geography of the worlds and of the earth occur in Chap. XII. The construction of the armillary sphere and its working and a mention of the main astronomical instruments form the subject matter of Chap. XIII. Chapter XIV enumerates and defines nine types of reckoning time, such as lunar, solar, sidereal, tropical, etc.

The *Sūryasiddhānta* is indebted to earlier astronomers like Āryabhaṭa (b. 476) and Brahmagupta (b. 598) in certain matters like the inclination of the planetary orbits, the tabular sines, etc. It is also to be noted that the *Sūryasiddhānta* does not include chapters on arithmetic, algebra, or astronomical problems, which are generally included in texts of this type.

The popularity of the *Sūryasiddhānta* is clear from the very large number of manuscripts of the work found throughout the land. About 35 commentaries on the work, written by scholars from different regions of India, and about 20 works, including planetary tables and manuals, based in the *Sūryasiddhānta*, have been identified. The popularity of the work is also reflected by the number of almanacs prepared on the basis of the *Sūryasiddhānta*.

Suśruta

Guy Mazars

Suśruta is not the original author of the medical ‘Compendium’ which bears his name, the *Suśrutasaṃhitā*, which constitutes the major source

of information about ancient Indian surgery. The treatise is supposed to contain the teaching of the god Dhanvantari, who was incarnated as Divodāsa, a king of Benares. Therefore it is not the personal work of Suśruta who had only recorded an already constituted medical tradition. The date of its redaction is not known. The basic text is supposed to have been revised and enlarged by an author called Nāgārjuna, which adds to the confusion, since there are several people named Nāgārjuna in Indian literary history. It is possible that the attribution of this name to the reviser of the text is but an echo of the legend which had the great Buddhist philosopher Nāgārjuna (first to second centuries AD) as a physician and alchemist. In any case, the teaching of Suśruta must already have been fixed at the time of the *Carakasamhitā* which refers moreover to the disciples of Suśruta for surgical treatment. The ‘Suśruta’s Compendium’ was the object of very elaborate commentaries whose purpose was to clarify and add precision to the contents. The principal commentaries of the *Suśrutasaṃhitā* are those of Jejjāṭa (before the ninth century), Gayadāsa (eleventh century) and especially that of ḍalhaṇa (eleventh to twelfth centuries) entitled *Nibandhasaṃgraha*.

In its present form the *Suśrutasaṃhitā* consists of 186 chapters which are divided into six large sections (*sthāna*):

1. Forty-six chapters in the *Sūtra* section deal with general questions such as medical training, diet or surgery.
2. Sixteen chapters in the *Nidāna* section deal with the diagnosis and prognosis of important ailments.
3. Ten chapters in the *Śārīra* section deal with the creation of the universe, embryology and anatomy.
4. Forty chapters in the *Cikitsā* section deal with therapy.
5. Eight chapters in the *Kalpa* section deal with poisons.
6. Sixty-six chapters in the *Uttara* section deal with diseases of the eye, ear, nose, and throat,

paediatrics, seizures by evil spirits, dentistry and internal diseases in general.

The *Suśrutasaṃhitā* describes surgical operations which reveal the skill and the daring of the surgeons of that period: the lowering of cataracts with a needle, grafts for repairing the nose and the earlobe, procedures for the removal of stones in the urinary tract, resections of scrotal elephantiasis, Caesarean sections and surgical removal of a dead foetus from the womb.

Swidden

Karl H. Schwerin

Swidden, also known as “slash and burn,” “long fallow,” and *roça* in Brazil, is a system of agriculture that involves clearing small areas within a forest, burning the slash (Figs. 1, 2, 3, and 4), and planting for 1–5 years (Figs. 5 and 6). The plot is then abandoned for 25–200 years – long enough

Swidden, Fig. 1 Mamo: uncleared swidden. Mamo, Venezuela. Uncleared farm plot thick with trees and undergrowth. Karinya Indians, March 1962 (Photo by Karl H. Schwerin)

Swidden, Fig. 2 Cachama: Field of Francisquito Martinez ready for burning. Cachama, Venezuela. Karinya Indians, February 1962 (Photo by Karl H. Schwerin)

for the forest to reclaim the cleared area. In contemporary Latin America this system may support as many as 50 million people.

In spite of the labor involved in clearing the forest, it is less than that required in clearing brush or turning under grass sod. This explains why fields are abandoned until the forest has regrown. In the tropics most nutrient and organic matter is locked up in the plants and trees, rather than in the soil. Thus, ash from the burned slash also frees nutrients for the crops.

A typical swidden planting mimics the diversity of the forest, with a variety of crops interspersed among each other, or planted in closely spaced zones within the field. In the Amazon-Orinoco drainages one may encounter 10–15 crops being grown together (Fig. 7). Once crops are planted, they require only one or two weedings before harvest (Fig. 8). In the tropics, harvest can extend over many months; just enough is taken from the field to provide for a few days or a week at a time. In a sense, then, the crop is stored in the field, rather than in a storehouse (Figs. 9, 10, and 11). The labor required in swidden is minimal, averaging 2–4 h a day

Swidden, Fig. 3 Cachama: Francisquito Martinez setting fire to field. Cachama, Venezuela. Karinya Indians, February 1962 (Photo by Karl H. Schwerin)

Swidden, Fig. 5 Mamo: planting manioc. Mamo, Venezuela. Juan Guevara planting a manioc cutting with his machete. Karinya Indians, March 1962 (Photo by Karl H. Schwerin)

(though perhaps concentrated into 5 or 6 h two or three times a week).

Swidden crops are often limited to starchy staples, vegetables, and fruits, producing little protein. Thus subsistence is typically supplemented by fishing and/or hunting. Only in Mesoamerica, where beans are important, is the need for supplementary animal protein reduced somewhat.

Swidden agriculture is often characterized as unproductive and destructive of soil fertility. In fact, during the first 1–3 years it is generally more productive than most permanent fields. The ash provides ready nutrients and there is little competition with other plants. The return on labor investment is even more rewarding.

After a few years productivity typically declines. Traditionally this was blamed on exhaustion of the soil. Extensive research indicates that this is due not so much to declining soil fertility, as to invasion by weeds and grasses which compete with crops for space and nutrients. A further motivation for abandonment is that this tangled growth becomes a magnet for vermin, insects, and

Swidden, Fig. 9 Cachama: Teresa Tamanaico pulling up manioc tubers. Cachama, Venezuela. Karinya Indians, July 1962 (Photo by Karl H. Schwerin)

disease. Thus the farmer logically seeks out a new spot in virgin forest to clear another plot free of problems (Fig. 12).

Contrary to popular belief, this does not necessitate periodic village movement. Robert Carneiro has shown that 500 people practicing swidden agriculture could subsist permanently on 6,000 acres located within a 3-mile radius of their village. Other explanations based on social, political, or religious factors must be sought for the practice of moving villages.

There is much debate about the “backward” and “deleterious” effects of swidden agriculture. When practiced by a sparse, widely dispersed population, it does not seem to harm the ecosystem, and may in fact prove beneficial by opening up the forest canopy and stimulating new growth. Some ecologists believe that the equilibrium state under aboriginal conditions was grounded on periodic swidden clearing. On the other hand, when population growth intensifies clearing to a point where the forest can no longer regenerate itself, the result will be widespread environmental degradation. Throughout Latin America recent programs of development

Swidden, Fig. 11 Cachama: Delia and Teresa Tamanaico stripping manioc tubers. Cachama, Venezuela. Karinya Indians, July 1962 (Photo by Karl H. Schwerin)

have led to widespread deforestation, replacement of swidden agriculture with more extensive systems such as livestock pasturing or machine cultivation, and resulting ecological degradation.

Tabiyah

Martin Malcolm Elbl
Maproom44 Ltd, Peterborough, ON, Canada

Ṭābiya, often called succinctly yet inaccurately “rammed earth,” has long been traditional architecture’s versatile alternative to concrete. The structures are strong, durable (given scheduled maintenance), and noncombustible, with a high thermal mass. They absorb heat during the day and radiate it at night. The embedded clays modulate interior humidity – the walls “breathe” better than concrete, with fewer condensation issues. As with cast-in-place concrete, the *ṭābiya* construction process involves shaping an initially ductile or pliable material. Instead of being poured as a slurry and left to set, a damp homogenized mix of low-clay (5–15 %) loamy earth, aggregate, and additives such as lime stabilizer and ash is compacted (tamped) in successive layers into a double-wall (box) formwork.

What makes the *ṭābiya* technique distinctive is its reusable modular wooden formwork that assembles by means of soft quick-connectors (traditionally mortise and tenon, wedges, pegs, tourniquet rope). Not all construction using earth as a component is *ṭābiya* fashion. The technique is a parallel invention of ancient origin, with antecedents reaching back to c. 5,000 BCE. Mundane as well as sacral structures and fortifications attests its use in various parts of Eurasia (notably China), the Middle East, Africa,

and the Mediterranean (Gandreau, Delboy, & Joffroy, 2012). In the Iberian Peninsula, *ṭābiya* is found in both pre-Roman and Roman contexts, but there is little evidence of significant use in Roman or Visigothic urban fortifications (Algorri García, Vázquez Espí, & de las Casas, 1996; Gurriarán Daza & Sáez Rodríguez, 2002).

The *ṭābiya* technique is inherently flexible and was always responsive to local availability and cost of materials as well as to project purposes. The implicit ecological benefit of traditional *ṭābiya* is that subsoils are typically used to obtain material, leaving leftover topsoil available for agricultural reuse. The ingredients in historically documented *ṭābiya* varied, as did workmanship and quality. Unlike with concrete, placing the ductile mix in the formwork was only a first step – expert and attentive compacting was key, and usually was left to the most experienced workers (even though the overall process is much less dependent on trained labor than masonry).

Terminology

Ṭābiya is an ambiguous term (as are the cognates *tapia* (Castilian), *taipa* (Portuguese), tappy, tabby (English), etc.). The relevant English language literature dating back to the 1980s and 1990s often offered, quite unfortunately, a truncated technical and historical context or operated with awkward renderings of foreign terms. This is particularly true of studies dealing with

derivative historic *tābiya* such as the “tappy” (“tabby”) of the Southeastern United States (northern Florida, Georgia, parts of South Carolina) (Davis & Taylor, 2006; Gritzner, 1978). The most comprehensive recent literature dealing with *tābiya* in the Mediterranean area and South America continues to be available mainly in Spanish, Catalan, or Portuguese only (for extensive bibliography, see, e.g., Graciani García, 2008; Gurriarán Daza & Sáez Rodríguez, 2002; Pavón Maldonado, 2012).

The primary meaning of *tābiya* is quite clear in Arabic sources as prominent as Ibn Khaldūn’s *Muqaddimah* (Ibn Khaldūn, 1967, Chap. 5, Sec. 24), which reserve the term for formwork processes and associate it with the noun *ṭawwāb* – “brick- or tilemaker,” the maker of *ṭūb* – an artisan often skilled in *tābiya* work as well. The association is not surprising. Where possible, the soil chosen for *tābiya* comprised fair to good potter’s or brick clay. The person best qualified to recognize suitable soils and guide their preparation was an expert *ṭawwāb*.

Tābūt (Arabic) (“coffer,” “box”) is the wooden (or modern metal-and-plywood) formwork as such, also referred to in the Western Maghrib as *lūh* (Standard Arabic *lawh*, “plank” or “board”). In Iberian technical usage, *tapia* (Castilian) (Portuguese *taipa*) mostly applies to the finished structure and *tapial* (Castilian) (Portuguese *taipal*) to the formwork (Graciani García, 2008; Pavón Maldonado, 2012; Torres Balbás, 1985). In the vernacular, the distinction formwork/structure often vanishes – *tapia* may denote any kind of wall (Castilian *pared*), just like *tābiya* may mean “fortress.” Other related terms (e.g., *pisé* and *pisé de terre* (French)) are equally problematic, especially now that PISE has become an acronym for “pneumatically impacted stabilized earth,” a mix of soil, Portland cement, and water (terrocement), sprayed from gunite machines against single-wall forms and rebar grids (Barbeta i Solá, 2002).

***Tābiya* Formwork, Ergonomics, and Work Flow**

Tābiya formwork typically includes the following basic components (Figs. 1 and 2). The

majority are reusable; those marked with an asterisk are expended in each setup:

- (a) Three putlogs* or three reusable “putlog” rods/needles (*aguja* (Castilian), *agulla*, *risell* (Catalan), *gato*)
- (b) Six main strongbacks (*costal* (Castilian), *cárcel* (Castilian), *aro* (Castilian), *travesaño* (Castilian), *barra* (Catalan))
- (c) Two side shutter assemblies (*tapial* (Castilian), *tapieres* (Catalan), *taules* (Catalan))
- (d) One end-shutter assembly (*frontera* (Castilian), *captauló* (Catalan))
- (e) Three tourniquet ropes (*soga* (Castilian), *soga* (Catalan)) and/or yokes (*brochal* (Castilian))
- (f) Ten or more assorted wedges
- (g) Three (optional) tourniquet pegs
- (h) Two or three (optional) spacer rods (*bastón* (Castilian), *bastó* (Catalan))

Historic types of formwork and many pre-1980s traditional ones were made entirely of wood (nails could be substituted with wooden dowels). Where available, tamarisk (gen. *Tamarix* (*tamariz*, *taray*)) was often used, particularly the larger of its 50–60 species. Tamarisk has a long history as a renewable source of utility lumber in drought-prone areas. Its drawback, however, is the limited gauge of lumber obtainable, particularly from deciduous species. The genus, native to the drier parts of Eurasia and Africa, can also become dangerously invasive (the salt cedar varieties are deemed an invasive species in the United States, where tamarisk spread artificially between the 1800s and the 1930s, as an ornamental and to inhibit erosion).

Putlogs were the only nonreusable parts of historic *tābiya* formwork. They generally remained embedded in the finished work (e.g., Figs. 1, 2, and 3) and were cut off flush once no longer required as formwork support. Mortar or other render (parging) protected the cut ends. Instances of putlog extraction for reuse, however, are not uncommon. In older or cheaper *tābiya* work, the putlogs were usually round (natural timber). From the mid-twelfth century, above all

Tabiyah, Fig. 1 Schematic model of basic *tābiya* formwork assembly using tourniquets (shuttering along the side facing the viewer omitted)

in the Maghrib and in the Iberian Peninsula, lumber with rectangular cross sections began to appear. In massive walls, e.g., fortifications, short putlogs only c. 45 cm long were used. These required special solutions to lock them in place. Wall thickness was flexible with short putlogs, and using squared lumber saved setup time, yet time was also lost in safe installation.

Subsequently, in Early Modern *tābiya*, particularly in the Iberian Peninsula, putlogs were gradually replaced in upscale construction by metal rods (*aguja*, *agulla*, *risell*, “needle”). These either passed straight through the work using holes left by spacer rods (*bastónes*) or were inserted halfway from each side (if equipped with eyelets). Coated with grease and fine sand before material was pitched in and tamped, *agujas* were more easily extracted and redeployed. The transition to metal rods saved

material and mitigated structural issues arising from the degradation of putlogs inside finished walls (Villanueva, 1827).

Formwork strongbacks (the vertical components that brace the shuttering) (Figs. 1, 2, 3, and 4) tended to be around 5 × 10 cm or heavier, roughly 1.3 m long. The lower end was shaped either to (a) straddle (fit *over*) the lumber or metallic putlog/needle or (b) to fit *into* the latter’s mortise or eyelet. Different local systems were devised. Where eyelet-equipped metal *agujas* were used, it was enough to whittle down the strongback’s tip to make it sit tight. If the tip was predrilled, in addition, to accept a safety peg below the eyelet, the peg locked the strongback in position. Alternatively, a tenon at the strongback’s end fitted into a mortise in the putlog. One might also mortise the strongback, to sit saddle-wise over the *aguja*, or drill it, to slip

Tabiyah, Fig. 2 Schematic model of basic *tābiya* formwork assembly using tourniquets and optional yokes (shuttering along the side facing the viewer included)

onto a round metal *aguja*. All the solutions required in principle a wedge fitting into a slit in the putlog/*aguja* (eye of the needle), to lock the strongback against the shutter.

The upper ends of the strongbacks took a variety of patterns (rope channel, knobhead, slight crook, end peg). All were designed to either (a) accommodate a rope tourniquet or other equivalent device and prevent it from riding up and coming off or (b) accommodate a wooden yoke. Tourniquet and yoke were not mutually

exclusive: the rope might be used to pull the strongbacks together as tight as needed and the yoke then installed for true rigid interlock. Either way, once the strongbacks were in position, wedged, or otherwise fastened below and under tourniquet tension or yoke interlock, they held the shuttering tight – at one end (in overlap) against the just finished block (also known as “lift”) and at the other end against the end shutter. The result was an empty rectangular compartment.

Tabiyah, Fig. 3 Schematic model of continuous-run *t̃ābiya* formwork assembly using braces, tie pegs, and short putlogs (based on hypothetical reconstruction in Graciani García (2008–2009, Fig. 8))

The side shutters most often comprised four boards each. Typically, the boards were 2–3.3 cm thick, 21–23 cm wide, and 2–3.3 m long. Ibn Khaldūn’s *Muqaddimah* gives 2 cubits as the most common module, which, if we suppose that the reference cubit was the *ma’mūnī* of 45 to 47 cm, would mean shutters at least 90 cm high and 1.9 m long, a little too high to be ergonomic (Ibn Khaldūn, 1967, Chap. 5, Sec. 24). The shuttering was held together by two small pieces of strongback (*montantes* (Castilian); c. 7.5 × 4.5 cm in cross section) nailed across the boards close to each end of the assembly, on opposing faces (Villanueva, 1827). Gaps of 2–3 mm

separated the boards, to let liquid expressed by tamping seep out and to allow for expansion from humidity saturation of the boards throughout a workday. A few simple cutout handholds at the ends and in the middle of the shutters (Fig. 2) made handling easier.

The end shutter was assembled using vertical or horizontal boards and a varying number of strongbacks, but one vertical board or strongback was usually left longer, as a handle. End shutters with arched tops were also common. Hammering on the handle or the arch reseated the shutter if it rode up in the course of tamping or unstuck the shutter if it did not come free readily during

Tabiyah, Fig. 4 Schematic model of continuous-run *tābiya* formwork assembly using braces, internal embedded grating, and short putlogs (an alternative to the hypothetical reconstruction in Graciani García (2008–2009, Fig. 8))

disassembly. End shutters of different sizes were used for different jobs. Together with the length of the putlogs/needles, they governed formwork width, unless short putlogs were used that did not traverse the work.

The width of the formwork was rarely an issue, unless the wall was so narrow that working high above ground, without added falsework (such as scaffolding) or safeties, became hazardous. Minimum wall width is normally governed by the formula $E = \text{height/width}$, where E should lie between 5 and 8, with 10 as the last safe value for non-reinforced one-story walls. Other calculations apply with a second or third story. Historic *tābiya* widths tend to range from 20 to 35 cm in

simple house walls (35 cm is preferred to facilitate compacting) to c. 80 cm in the walls of hollow fortification towers, for instance, and 2 m or more in massive curtain walls of urban fortifications (Graciani García, 2008; Graciani García, 2008–2009; Graciani García & Tabaes Rodríguez, 2003; Pavón Maldonado, 2012).

The keys to the ergonomics of *tābiya* were elbow room and weight of the components (Barbeta i Solá, 2002). If the weight of each side shutter is kept around 25 kg, assembly, disassembly, and moving the components to the next position can be a one-man task. Light shutters also permit skinnier putlogs. The shutters are in fact lifted entirely off putlogs only when work

comes to a corner block. In a straight wall run, placing the next batch of putlogs and moving the strongbacks is sequenced so that the shutters simply slide forward on the putlogs while remaining restrained by partially loosened strongbacks. The round timber putlogs or round metal *agujas* are slick – like the shutter itself – with seeping mud and liquid, making this an easy operation.

The optimal weight factor constrains shutter length/height and board thickness. Length also has to be balanced against the minimum number of strongbacks required. These would preferably have to be added in modular increments, at 0.75–0.85 m spacing. The spacing, just like optimal height for standard formwork (max. 0.85 m), was namely calibrated to the elbow room required by a worker wielding an old-style manual rammer and to the muscle fatigue from raising the rammer repeatedly to a given height. The most common traditional arrangement was a fairly optimal one. Typically, there were three strongbacks a side, spaced c. 0.75–0.85 m on center (Barbeta i Solá, 2002). Archaeology has documented, however, a gradual increase in the distance between strongbacks (and thus putlogs) in the Iberian Peninsula, from c. 0.5 m on center in early *ṭābiya* work to c. 0.85 m from the middle of the twelfth century CE (Graciani García & Tabales Rodríguez, 2003) (Table 1, Fig. 5).

Materials and Preparation

The basic ingredients are low-clay loamy earth, aggregate, and controlled quantities of stabilizer. Various optional additives were used or experimented with in different historic and regional contexts. Estimating the required volume of raw earth must factor in losses incurred

in sifting and premixing, transport, and compacting (around 30–45 % for the latter alone). The material should not contain stones larger than a fist and should be free of all vegetable matter. Greasy material (excess clay) tends to stick to the formwork and shrinks too much. Sticky formwork can take patches of material out of the finished surface when being dismounted. Finished blocks that shrink excessively also develop fractures and deformations (Gurriarán Daza & Snacel Sánchez, 2014; Villanueva, 1827).

The prepared material must be kept moist (not wet) and should be pitched into the formwork at more or less optimal stiffness. The traditional test was to squeeze a fistful of the material – if it did not stick to the hand and kept the imprinted shape, it was good to go (Villanueva, 1827). Technically, the optimal point stands around 12 % TEO on a Proctor test. Too little moisture prevents adequate homogenization; too much moisture results in blocks with lower compression strength that also abrade easily (Barbeta i Solá, 2002). Part of the moisture is expelled through compacting. As stabilizer, lime or animal blood was used. Alternatives and modern replacements include lime, cement, or various asphalt emulsions. The latter entail commonly recognized drawbacks.

Each block was built up inside the formwork incrementally. Material was pitched in and spread in a layer 7–25 cm deep (7–10 cm being optimal) and compacted to about 50 % of the original loose depth. Traditional tamping was manual, using wooden rammers. This is labor intensive and requires both endurance and adequate care, and fatigue can produce uneven compacting. Once a block has been completed, it is sturdy enough and has already lost enough

Tabiyah, Table 1 Basic formwork dimensions in historic and traditional *ṭābiya* preparation

	Height	Length	Traditional base unit
<i>Standard (Maghrib and al-Andalūs)</i>	≤0.80 m		<i>rassāsī</i> cubit (54.07 or 58.8 cm)
<i>Oversize (Maghrib and al-Andalūs)</i>	0.90–0.94 m	2.25–2.50 m	two <i>ma'mūnī</i> cubits (2 × 45 to 47 cm)
<i>Traditional (optimal)</i>	c. 0.81 m	2.20 m	
<i>Traditional (reported)</i>	c. 0.84–1.19 m	2.46 m	
<i>Theoretically ergonomic</i>	max 0.75–0.85 m	max 2.00 m	–

Finished wall with leveling courses (*verdugadas*) of stone or brick (schematic view)

Finished wall with leveling courses (*verdugadas*) and corner blocks (pilasters) (*cadenas*) of stone or brick masonry (schematic view)

Tabiyah, Fig. 5 Schematic model of finished *tābiya* wall segments with leveling courses (*verdugadas*) and masonry blocks (*cadenas*)

moisture for the formwork to be removed almost immediately and set up for the next block. Workflow is continuous. No setting-in-the-form period is involved, unlike with concrete. The surface usually becomes too difficult to work within the hour, and any texturing (texturing to improve the bonding and adhesion of a sealing coat) must be done as soon as the formwork comes off (Barbeta i Solá, 2002).

It was common procedure to flip the side shutters end for end once a corner was reached, i.e., when the shutters were being lifted entirely off. The flipping ensured that shutter faces were exposed to humidity and pressure from inside the formwork evenly over a workday. In principle,

formwork should never be left mounted overnight, to prevent warping the boards. Incidentally, as the two pieces of strongback (*barzones* in Castilian) that hold the boards together and also serve as end shutter stops are nailed across opposite faces, one of these will automatically end up on the outside (permitting a snug flat fit to the side of the just finished block), while the other will be on the inside, to serve as a stop. The process thus differs from modern concrete forming by means of treated plywood shutters – the vast majority of standard premade shutter assemblies (on wood or metal frame) normally always expose the same working side of the plywood sheet to the concrete (Barbeta i Solá, 2002).

Compressive strength of a finished *ṭābiya* wall and associated components increase gradually with drying and curing. Complete curing may take up to 2 years or longer, depending on materials. The results of compressive strength tests on various samples from historic *ṭābiya*-made structures range widely, from 25.5 kg/cm² (362.7 psi) for household and utility walls to between 184 and 213 kg/cm² (2,617.1–3,029.6 psi) for high-grade fortifications (e.g., Barbeta i Solá, 2002; Graciani García, 2008, pp. 144–145). *Ṭābiya* that incorporates lumber, bamboo, lime concrete, brick, stone masonry, or in modern versions steel rebar reinforcements, in various configurations, offers superior structural resilience and limited anti-seismic properties.

Varieties of *Ṭābiya*

A raw finished *ṭābiya* wall, just like raw finished cast-in-place concrete, displays formwork marks (mostly horizontal raised lines at the seams between formwork sections). In addition, a sequence of horizontal strata from the layered compacting is often visible. Weathering may accentuate the inherent pattern. Some of the standard observed patterns are useful for initial historical and structural diagnosis as well as for dating *ṭābiya*-made monuments. The following key types are for the most part readily identified through preliminary surface pattern and texture analysis:

- (a) Plain clayey earth *ṭābiya* (*tapia de tierra* or *tapia ordinaria* (Castilian)) without optional additives and even without stabilizer.
- (b) Stabilized homogeneous block *ṭābiya* (*tapia estabilizada en masa* (Castilian)) using gypsum or lime as binders (in particular kiln lime with various degrees of hydraulicity) and aggregate ranging from sand to pebbles, pieces of rock, crushed ceramic tile, and brick rubble. In transatlantic contexts (Brazilian and early American colonial “tabby” or “tappy”), lime was often obtained not from limestone but from seashells.
- (c) Reinforced block-joint *ṭābiya* (*tapia de tierra y cal* (Castilian)), in which the horizontal and vertical joints between blocks formed by compacting consist of lime or gypsum mortar (in the latter case, the finished product is a *tapial de tierra y yeso* (Castilian)).
- (d) Reinforced crust/casing *ṭābiya* (*tapia de tierra crostada*, *tapia calicastrada*, or *calicostrada* or *acerada* (Castilian)), in which a layer of mortar ranging in thickness from 1.5 to as much as 15 cm is applied on both sides to the forming boards, up to the estimated height of the first layer of clayey earth mix to be compacted, and then the process is repeated for each successive layer until block completion. The result is a *ṭābiya* block encased in tight-bond mortar coating. In cheaper varieties, only the exterior face of a wall would be so treated, not the one facing the building’s interior.
- (e) Reinforced crust-and-layer *ṭābiya* (*tapia crostada con juntas de mortero de cal*) in which the process of making a reinforced crust/casing *ṭābiya* is further enhanced by spreading a horizontal layer of mortar on top of each compacted layer of earth mix. The mortar crust and the layers of mortar separating the earth-mix layers interlock as they cure, enhancing rigidity and offering greater erosion resistance.
- (f) Reinforced *ṭābiya* with mixed-material structural components (various types of *tapia mixta*, *tapia verdugada/encadenada*, or *tapia de fraga* (Castilian)). These types of *ṭābiya* represent a logical high-cost extension of the crust-and-layer design. They feature (a) highly visible distinctive horizontal leveling courses of masonry (rough stone, ashlar, brick, single course to as thick as triple course) between the compacted *ṭābiya* blocks and (b) vertical masonry blocks (*cadenas*) either reinforcing structural corners or flanking and separating the *ṭābiya* blocks (the latter type of construction is usually called *de cajones únicos*). The *cadenas* play a structural role similar to the vertical ashlar blocks in Carthaginian and Roman *opus africanum*. Leveling courses alone, *cadenas*

alone, leveling courses with corner *cadenas*, and leveling courses with massive *cadenas* and homogeneous blocks of *tābiya* fill have been used in varying combinations. Specific combinations permit approximate dating of historic structures.

Takebe Katahiro

Shigeru Jochi

Osaka Kyoiku University (Osaka University of Education), Osaka, Japan

Takebe Katahiro was born in 1664 at Edo (now Tokyo). His father, Takebe Naotsune, was a *Yuhitsu* (secretary) of the Shogun. In 1676, when he was 13 years old, he and his elder brother Takebe Kataaki (1661–1716) became pupils of SEKI Kowa (d. 1708) and studied mathematics.

The Takebe brothers and ► [Seki Kowa](#) were colleagues in the Shogun's government, and their families were the same rank: 300 *koku*. (His annual salary was 300 *pyo* (1 *pyo* was 60 kg of rice), which is the same as a landlord of 300 person village.)

Takebe's mathematical works are in three fields. One concerns completing the *tenzan-jutsu* or *endan-jutsu* (lit. addition and subtraction methods, Japanese algebra system), which was created by Seki Kowa. In the second work Takebe created the *tetsu-jutsu* (inductive methods). Using these methods he obtained the formula of $(\arcsin \theta)^2$. In the third, for computing the approximate value of fractions, he solved the Diophantine equations using the *reiyaku-jutsu* (continual division method). Takebe also worked in astronomy and geography.

In 1683, Takebe wrote his first work, *Kenki Sampo* (Studies for Mathematical Methods). The book provided counter-arguments for Saji Ippei's *Sampo Nyumon* (Introduction to Mathematical Methods, 1680). Saji had criticized Seki Kowa's *tenzan-jutsu* system in the *Hatsubi Sampo* (Mathematical Methods for Finding Details, 1674) and solved Ikeda Masoki's problems in the *Sugaku Jojo Orai* (Textbook of Mathematical Multiplication and Division, 1672). Takebe made good use of the *tenzan-jutsu* method for solving Ikeda's remainder problems.

Takebe commented on Seki Kowa's *Hatsubi Sampo* and published the *Sampo Endan Genkai* (Commentaries for Japanese Algebra System), in 1685. This is one of the best books for studying the *tenzan-jutsu* method.

Chinese mathematicians in the Song and Yuan dynasties used counting rods to solve higher degree equations of more than the fourth degree. There were two color symbols in the counting rods: red rods were plus and black were minus. They had no symbols to express power; the position of the rods on the counting board indicated the powers. Therefore, the system could not indicate complex expressions. For example, $1/(x-1)$, that is $(x-1)^{-1}$, was very difficult to indicate by that system. Seki Kowa abandoned the counting rods system and created algebraic symbols, which used Chinese characters for

calculation with figures. This might be the first example of creating Japanese mathematics from the Chinese.

Takebe commented on the most important Chinese algebraic text in Japan at that time, *Suanxue Qimeng* (Introduction to Mathematical Studies, Zhu Shijie, 1299). He published the *Sangaku Keimo Genkai Taisei* (Complete Works of Commentaries on Suan Xue Qi Meng) in 1690. Seki Kowa and the Takebe brothers started to compile an edition of the mathematical works of *Seki-ryu*, Seki Kowa's school. After Seki died, Takebe Katahiro continued this work and published *Taisei Sankyo* (Complete Mathematical Manual) about 1710.

Takebe's main work is the *tetsu-jutsu* method, a sort of inductive method. He computed small natural numbers and then predicted infinite numbers. The computation was helped by the algebraic symbols of the *tenzan-jutsu* method. Using these methods, Takebe obtained the formula of $(\arcsin \theta)^2$. He computed the length of curve AB (hereafter s) using the diameter d and the length of straight line AB (h).

Takebe set up $d = 10$ and $h = 10^{-5}$. Then letting the half point of straight line AB be C_2 , and the half point of curve AB be B_2 , he computed the length of AB_2 (h_2). Then he computed the length of AB_4 as h_4 , and continued to compute h_8, h_{16}, h_{32} and h_{64} . Takebe computed h_∞ using a sort of infinity series *zoyaku-jutsu* (extra division method), and obtained h_∞ .

$$\begin{aligned} \left(\frac{s}{2}\right)^2 &= 10^{-4} \times 1.000\ 000\ 333\ 333\ 411\ 111 \\ &\quad 225\ 396\ 906\ 666\ 728\ 234 \\ &\quad 776\ 947\ 959\ 587 \\ h(AC_2B) &= 10^{-5}, \\ d(B_2OD) &= 10^1. \end{aligned}$$

Second, he indicated this value using h and d . The power 10^{-4} is h by d , and the approximate value of the coefficient is 1. Therefore,

$$\begin{aligned} \left(\frac{s}{2}\right)^2 &= 1hd + 10^{-10} \\ &\quad \times 0.333\ 333\ 511\ 111 \dots \end{aligned}$$

Then he used the same method. The power 10^{-10} is h^2 , and the approximate value of the coefficient is one-third using the *reiyaku-jutsu* method,

$$\left(\frac{s}{2}\right)^2 = 1hd + \frac{1}{3h^2} + 10^{-16} \\ \times 0.177\ 777\ 992 \dots$$

Takebe continued to compute as above, and he set the series as

$$\left(\frac{s}{2}\right)^2 = A_0 + A_1 + A_2 + A_3 + A_4 + \dots$$

He obtained

$$A_0 = hd, \quad \frac{A_1}{A_0} = a_1 \left(\frac{h}{d}\right), \\ \frac{A_2}{A_1} = a_2 \left(\frac{h}{d}\right), \quad \frac{A_3}{A_2} = a_3 \left(\frac{h}{d}\right), \dots \\ a_1 = \frac{1}{3}, \quad a_2 = \frac{8}{15}, \quad a_3 = \frac{9}{14}, \quad a_4 = \frac{32}{45}, \dots$$

He expanded them to the general series of a_n , which was

$$A_n = \frac{2n^2}{(n+1)(n+2)}.$$

Therefore Takebe obtained the formula

$$\left(\frac{s}{d}\right)^2 = 2 \sum_{n=0}^{\infty} \left(\frac{(n! \times 2^n)^2}{(2n+2)!} \times \frac{h^{n+1}}{d^{n-1}} \right).$$

Takebe had no notion of triangle functions. However, if we set

$$\theta = \sqrt{\frac{h}{d}},$$

we can obtain $\arcsin \theta = s/(2d)$. Therefore, his formula has the same value as the formula

$$(\arcsin \theta)^2 = 2 \sum_{n=0}^{\infty} \frac{(n! \times 2^n)}{(2n+2)!} \times \theta^{2n+2}.$$

This work was described in the *Fukyu Tetsu-jutsu* (Inductive Methods) in 1722, and the special manuscript was sent to Shogun in 1730.

The key method of *tetsu-jutsu* was computing the approximate value of decimal fractions. He named it the *reiyaku-jutsu*, which used the Euclidean algorithm to compute the value of continuing fractions. For example, to try to compute the approximative value of π using this method, we set;

$$\pi_n = 3.1415926, \quad \text{or} \quad 3 + \frac{1,415,926}{10,000,000}.$$

First, divide 10,000,000 by 1,415,926; the quotient q_1 is 7 and the remainder r_1 is 88,518. Next, divide the former divisor 1,415,926 by the remainder r_1 ; the quotient of q_2 is 15 and the remainder r_2 is 88,156. Next, divide the former divisor r_1 by the newer remainder r_2 , and the quotient q_3 is 1 and the remainder r_3 is 362. Continuing this algorithm, the quotients are:

- $\{q_1, q_2, q_3, \dots, q_n\} = \{7, 15, 1, 243, 1, 1, 9, 1, 1, 4\},$
- $p_1 = 3 + 1/7 - 22/7 > \pi_n,$
- $p_2 = 3 + 1/(7 + 1/15) = 333/106 < \pi_n,$
- $p_3 = 3 + 1/(7 + 1/(15 + 1/1)) = 355/113 > \pi_n.$
- $p_{2k} = q_0 + 1/(q_1 + 1/(q_2 + 1/(q_3 + 1/(q_4 + \dots + 1/q_{2n} + 1)))) < \pi_n,$
- $p_{2k+1} = q_0 + 1/(q_1 + 1/(q_2 + 1/(q_3 + 1/(q_4 + \dots + 1/q_{2n} + 1)))) > \pi_n.$

The value of p_1 and p_2 had already been computed by the Chinese mathematician, ► [Zu Chongzhi](#) (429–500). Takebe concluded that Zu Chongzhi also invented the same method as his own *reiyaku-jutsu* and Zu Chongzhi's significant figures were seven decimal places, the same as the above computation. He admired Zu Chongzhi and named his book *Fukyu Tetsu-jutsu*; the title was connected with Zu Chongzhi's *Zhui Shu*.

In 1723, Takebe made a map of Japan under the order of Tokugawa Yoshimune, the eighth Shogun, this map is now lost. That year Takebe became a *Yoriai* (adviser) of the Shogun.

Shogun Yoshimune already permitted the import of foreign scientific books in 1720,

if they were not related to missionaries. Knowledge of Western astronomy was imported in some Chinese translations. Takebe and his student, Nakane Genkei (1662–1733) translated Mei Juecheng's *Li Suan Quan Shu* (Complete Works of Calendar and Mathematics, 1723) and sent the manuscript (Japanese name *Rekisan Zensho*) to Yoshimune in 1733. It was published and read by many Japanese scholars. Kepler's newest opinion, the elliptical orbit of planets, however, was hidden by the missionaries who advised Mei Juecheng. It became known to the Japanese after ► [Asada Goryu](#) (1734–1799) translated Kepler's (Part 2 of) *Li Suan Quan Shu*.

Takebe was held in honor by Yoshimune, and he became a *Hoi* (Knight), and held successively better positions. In 1733, he retired, and he received a life annuity of 300 *pyo*. He died on July 20, 1739 (August 24, 1739 in the present calendar) at Edo.

Takebe was one of the best mathematicians in Japan. The Mathematical Society of Japan has presented the Takebe Katahiro Prize since 1996.

Tang Shenwei

Hong Wuli

Tang Shenwei was a medical practitioner of the eleventh century. He was a native of Chongqing, Sichuan Province with the surname Shenyuan, and later he moved to Chengdu in the same province. He was born to a family of many generations of physicians and was an expert in medical science. During the Yuanyou period (1086–1094) of the Song Dynasty, his tutor was Li Duanbo. Tang inherited his tutor's medical knowledge and became quite adept at treatment. He was very virtuous, also he responded to any patient's call and never refused to see a patient, whether rich or poor. The only payment he asked was knowledge about a certain herb or an effective recipe (Tang, 1957).

He was especially conversant in the herbal art. He compiled a 32-volume *Materia Medica of Classified Syndromes* which was based on the combination of two other existing herbological works, the *Jia you ben cao* (*Jiayou Materia Medica*) and *Tu jing ben cao* (*Illustrated Classic of Materia Medica*). He added a large amount of new material extracted from the classics of philosophy, history, and other branches of the natural and social sciences, as well as the Buddhist canon, with a total number of 1,746 herbal drugs (Tang, 1904). In the field of traditional pharmacology, in addition to absorbing the knowledge inherited from earlier practitioners, he was full of initiative and creativity. Most of his experience was derived from his own long-term practice. He enriched the traditional herbological work by adding processing methods and effective recipes for each herb. Meanwhile, he was also a proficient clinical physician. He created a new style of combining medical practice with herbal knowledge to form the principle of “verifying the drug by recipes,” which was quite helpful to clinical practitioners, thus pushing medical science forward a step further. His work was treated as an officially promulgated book on materia medica

and circulated for several hundred years (Shang et al., 1989). His working methodology and epistemology were praised and copied by later scholars in the same field. Tang exerted an especially profound influence on the work of the great naturalist of the Ming Dynasty, ► [Li Shizhen](#).

Tao Hongjing

Fabrizio Pregadio

The Daoist (Taoist) master, alchemist, and pharmacologist Tao Hongjing was born in 456 near modern ► [Nanjing](#). He served in various positions at the courts of the Liu Song and Qi dynasties until 492. In that year he retired to Mount Mao, the seat of Shangqing or Supreme Purity, a Daoist tradition based on meditation and visualization techniques. The retreat he built on the mountain was to remain the center of his activities until his death in 536.

After his initiation into Daoism around 485, Tao set out to recover the original manuscripts, dating from about one century before, that contained the revelations at the source of the Shangqing tradition. Tao authenticated and edited the manuscripts, and wrote extended commentaries on them. This

undertaking resulted in two texts completed in ca. 500, the *Zhengao* (Declarations of the Perfected) and the *Dengzhen yinjue* (Concealed Instructions on the Ascent to Perfection, only partially preserved). These and other works make Tao Hongjing the first systematizer of Shangqing Daoism, of which he became the ninth patriarch.

Since the establishment of the Liang dynasty in 502, Tao enjoyed the favor of Emperor Wu (r. 502–549), on whom he exerted remarkable influence. Shortly after, he began to devote himself to alchemical practices under imperial patronage. His main biographical source, written in the Tang period, has left a vivid account of these endeavors. Along with scriptural sources they testify to the importance of alchemy within the Shangqing tradition, which represents the first known instance of close links between alchemy and an established Daoist movement.

A third text on which Tao Hongjing worked during his retirement on Mount Mao was the *Bencao jing jizhu*, a commentary on the earliest known Chinese pharmacopoeia, the *Shennong bencao*. The original text contained notes on 365 drugs. To these Tao added 365 more, taken from a corpus of writings that he refers to as “Separate Records of Eminent Physicians.” Tao’s arrangement of the materia medica was also innovative. He divided drugs into six broad categories (minerals, plants, mammals, etc.), and retained the three traditional classes of the *Shennong bencao* only as subdivisions within each section. In a further group he classified the “drugs that have a name but are no longer used [in pharmacology].” Tao’s commentary discusses the nomenclature, notes changes in the geographical distribution, and identifies varieties; it also includes references to the Daoist *Xianjing* (Books of the Immortals) and to alchemical practices. With the exception of a manuscript of the preface found at Dunhuang, the *Bencao jing jizhu* is lost as an independent text, but has been reconstructed based on quotations in later sources.

Taqī Al-Dīn

Sevim Tekeli

Taqī al-Dīn, Muḥammad al-Rāšid ibn Ma'rūf, was a mathematician and astronomer. He was born in Damascus in 1521 and died in about 1585. He wrote several books on mathematics, astronomy, optics, and theology.

The most important of his books are: *Jabr wa'l-Muqābala* (Algebra), *Bughyat al-Ṭullāb min 'ilm al-Ḥisāb* (The Desire of Students for Arithmetic), *Sidrat al-Muntahā fī al-Afkār* (The Nabk Tree of the Extremity of Thoughts), and *Ālāt-i Raṣdīya li Zīj-i Shāhinshāhīya* (Observational Instruments of the Emperor's Catalogue), *Al-Kawākib al-Durrīya fī Bengamāt al-Dawrīya* (The Brightest Stars for the Construction of Mechanical Clocks).

From the point of view of the history of Ottoman science, the most important event of the sixteenth century was the foundation of the Istanbul Observatory, which Taqī founded under the sponsorship of Murād III (1574–1595). This observatory was an elaborate building which

contained dwelling places, a library, and offices for the astronomers. It was conceived as one of the largest of the observatories of Islam and was comparable to Tycho Brahe's (1546–1601) Uraniborg Observatory built in 1576, equipped with the best instruments of his time in Europe. There is a striking similarity between the instruments of Tycho Brahe and those of Taqī al-Dīn.

The instruments of the observatory included the following. First there were those originally constructed by Ptolemy: the armillary sphere, the parallactic ruler, and the astrolabe. Then there were those invented by Muslim astronomers, such as the azimuthal and mural quadrants. Taqī al-Dīn invented the *mushabbaha bi'l manāṭiq* (sextant, an instrument with cords for the determination of the equinoxes), which was also an important invention of Tycho Brahe. In addition, he built a wooden quadrant for the measurement of azimuths and elevations, and clocks for the measurement of right ascensions of the stars. The latter was one of the most important discoveries in the field of practical astronomy in the sixteenth century, because in the beginning clocks were not accurate enough to be used for astronomical purposes.

In *The Astronomical Instruments of the Emperor's Catalogue* the author says, "The ninth instrument is an observational clock." The following statement is taken from Ptolemy: "I could have freedom of action if I were able to measure the time accurately. Now our master Taqī al-Dīn, with the help of God, upon the instructions of the Sultan, planned the observational clocks." In *The Nabk Tree of the Extremity of Thoughts* Taqī al-Dīn says, "We constructed a mechanical clock with three dials which show the hours, the minutes, and the seconds. We divided each minute into 5 s." On the basis of his observations, Taqī al-Dīn prepared astronomical catalogues and books.

Hipparchos (second century BCE) used the intervals of seasons for the calculation of the solar parameters. But the variation of the declinations around the tropics in 1 day rendered difficult the correct determination of the beginning of the seasons. In spite of this difficulty, the method was used for a long time.

After him, ► [al-Bīrūnī](#) (d. ca. 1048), Copernicus (1473–1543), and Tycho Brahe were interested in this subject, and used a new method called “three points observation.” Taqī al-Dīn, a contemporary of Tycho Brahe, says the following in *The Nabk Tree*: “The moderns follow the method of three points observation, two of them being in opposition in the ecliptic and the third in any desired place.” This method was an important contribution to astronomy. By using this method, Copernicus, Tycho Brahe, and Taqī al-Dīn calculated the eccentricity of the orbit of the Sun, and yearly mean motion of the apogee. According to Copernicus the eccentricity is 1p 56′; according to Tycho Brahe it is 2p 9′, and according to Taqī al-Dīn it is 2p 0′ 34″ 6''' 53''' 41'''' 8''''' . As compared to modern calculation, Taqī al-Dīn’s is the most accurate value. According to Copernicus the annual motion of the apogee is 24″; to Tycho Brahe it is 45″, and to Taqī al-Dīn it is 63″. Its real value is 61″. As far as world astronomy is concerned, Taqī al-Dīn’s results can be said to be the most precise in the calculation of solar parameters.

The next important contribution of Taqī al-Dīn concerns the use of decimal fractions, the system of numerals formed from initial letters, used in the Hellenic world. This system hindered the development of algebra.

► [Al-Khwārizmī](#) (d. 801) presented the decimal system which was inspired by Indians to the Islamic world. The application of this to fractions started with Abū’l-Ḥasan Aḥmad ibn Ibrāhīm al-Uqlīdīsī and continued with al-Kāshī (d. 1437). But its application to astronomic and trigonometric tables was realized by Taqī al-Dīn. Thus the tables of his ► [zīj](#) named *Kharīdat al-Durar* (*unbored pearl*) and a *zīj* were prepared using the decimal system and decimal fractions.

Tattooing in China

Carrie E. Reed

Middlebury College, Middlebury, VT, USA

Evidence for the practice of tattoo in early China can be found in a number of texts that date from the mid-first millennium BCE to the nineteenth century CE. These works include *Shangshu* 尚書 (*Hallowed Documents*); *Liji* 禮記 (Record of Rites); *Zhuangzi* 莊子; dynastic histories starting with the *Shiji* 史記 (*Records of the Historian*); literary anthologies such as *Wenxuan* 文選 (*Selections of Refined Literature*); dynastic penal codes; and informal narrative collections

such as *zhiguai* 志怪 (records of anomalies) and *biji* 筆記 (note-form records).

In these texts at least six types of tattoo are mentioned: tattoo marking a people as different from the majority population, tattoo as punishment, tattoo of slaves, tattoo in the military, figurative tattoo, and textual tattoo. These types sometimes overlap; a formerly branded slave or criminal might join the army and be marked with his regimental brand. Later he might voluntarily have his body tattooed with complex figures or texts. After leaving the army, he might join a gang of street toughs and further tattoo his body.

The terms used for tattoo are varied and inconsistent; neither tattoo as punishment nor as decoration is always called by the same name, even in the same time period. Some of the terms encountered in these early texts are *qing* 黥 (to brand, tattoo), *mo* 墨 (to ink), *ciqing* 刺青 (to pierce [and make] blue-green), *wenshen* 文身 (to pattern the body), *diaoqing* 雕青 (to carve and [make] blue-green), *juyan* 沮顏 (to injure the countenance), *wenmian* 文面 (to pattern the face), *limian* 斲面 (to cut the face), *huamian* 畫面 (to mark the face), *loushen* 鏤身 (to engrave the body), *louti* 鏤體 (same), *xiumian* 繡面 (to embroider [or ornament] the face), *kenie* 刻涅 (to cut [and] blacken), *niezi* 涅字 (to blacken characters), *cizi* 刺字 (to pierce characters), and so on. These terms are sometimes used together, and there are numerous further variations.

In almost all of the textual sources, tattooed people are stigmatized as defiled or uncivilized. Mainstream, educated Chinese society never accepted the practice as normal or acceptable. This opprobrium was partly due to the association of tattoo with somewhat “barbaric” people on the periphery of society, whether foreigners, prisoners, or military men. Also, in the traditional Confucian worldview, it is unacceptable for a person to defile the body given to one by one’s parents.

Several early sources mention the tattooing practices of peoples in the areas surrounding the central kingdoms. Among others, the records refer to Man 蠻 or Yi 夷, broad terms that refer to various tribes located mostly south of the Yangzi River, from what are now Guangdong

and Vietnam to the south, to Zhejiang and Jiangxi to the north. Other peoples that are described as tattooed are the people of Wo 倭 (present-day Japan) and Liuqiuguo 流求國 (modern-day Taiwan). The various “others” in these passages are often described as being tattooed with animal patterns or fish scales, presumably as apotropaic aids to avert the danger from ferocious creatures in the wild, mostly riverine areas where they lived. The specific customs described by Chinese literati in these texts vary, but the purpose of most of the passages is to highlight the differentness of the tattooed peoples. This sense of otherness is strengthened by the mention of activities such as eating raw meat or eating with the hands and going about naked; from the point of view of a civilized Chinese person, these are habits hardly different from those of animals. Tattoo is portrayed as the epitome of uncivilized practices since it renders the human body patterned like the skin of an animal or water creature.

Tattoo, like the other corporal punishments, was an effective means of punishment in China for most of recorded history, due to the shame that a criminal felt upon reentering society with parts of the body either mutilated or even removed, permanently marking him or her as untrustworthy. From early times until recently there has been a strong stigma attached to failing to preserve one’s physical body. By not keeping the body intact and undefiled, one has failed in one of the most important filial duties and has brought shame on one’s family –past, present, and future. In the very beginning of the *Xiaojing* 孝經 (*Classic of Filial Piety*), Confucius tells his disciple Zengzi 曾子 that filial piety is the thing most necessary for civilized society and that the basis of filial piety lies in avoiding injury to the skin, hair, and body that one receives from one’s parents. The existence of this kind of social pressure must have made punishments such as the injuring of the skin by tattoo or branding particularly fearful.

Although tattoo theoretically was abolished, along with the other mutilating punishments, by Emperor Wen 文帝 (r. 179–155 BCE) in 167 BCE, it was continued as a punishment during the Han 漢 (206 BCE–220 CE) and the

following period of disunion. There is no mention of tattoo in the Tang 唐 (618–907) penal code though examples of the actual continuation of the practice are to be found in the histories and in *zhiguai* texts. It was reinstated as a legal form of punishment after the Tang, and there are many references to it in later dynasties. It was often combined with exile, as a way to ensure that the defiled person be removed as far as possible from law-abiding, civilized people. For example, the “punishment treatise” of the *Songshi* 宋史 (*History of the Song dynasty*) states that there are 200 crimes punishable by tattoo and banishment. Among these, in the case of relatively minor offenses, the punishment might be lightened to banishment alone, but if the criminal were to commit another crime, he would be tattooed at once and enlisted in the military.

A few special types of tattoo pertain naturally only to slaves, such as the facial brand of ownership or the forehead brand identifying a person as someone who had attempted escape. In addition, there are some records that describe women forcibly tattooing the faces of their slaves or their husband’s concubines, to render them unattractive to males in the family.

It is likely that a large percentage of tattoos after at least the Han dynasty were in some way connected with the military. In some eras there was a practice of branding soldiers with post and rank to prevent escape and absenteeism and as a way to mark prisoners of war. Tattoo was likely a method of identifying bodies on the battlefield as well. Also in at least one time of upheaval, ordinary citizens were seized and tattooed as slaves of the armies. When these people escaped, they were forced to form gangs of bandits to survive until a general amnesty allowed them to return to their villages.

One kind of military tattoo is the oath, whereby a soldier could tattoo dedication to a certain cause. An entire regiment could be tattooed with a symbol or a short phrase, or individual soldiers might tattoo themselves. The most famous example of the latter was the Song General Yue Fei 岳飛 (1103–1141), heroic subject of many plays and stories focusing on his attempts to recapture northern China from the Jurchens.

His biography says briefly that he had a tattoo on his back reading “Jin zhong bao guo” 盡忠報國 (serve the nation with absolute loyalty). A *chuanqi* drama about this story vividly portrays Yue Fei’s mother crying as she pierces her son’s skin with an embroidery needle and rubs ink into the wounds.

Perhaps not so unlike the military soldiers and heroes, lovers sometimes tattooed their skin to represent an oath of shared commitment. And, like these oath tattoos, various other kinds of representative tattoos were sometimes done voluntarily. There is evidence that all manner of people practiced tattoo, in spite of the stigma. These included emperors and outlaws, street thugs, and robed officials.

The best-known literary treatment of tattooed men is that found in the sixteenth-century vernacular novel *Shuihuzhuan* 水滸傳 (*Outlaws of the Marsh*). The story features five tattooed men in the band of outlaws that gathers under the leadership of Song Jiang 宋江 at Liangshan Marsh; Song Jiang’s tattoo is a facial brand, and the others are figurative. Shi Jin 史進, for example, is known as the “Nine-Patterned Dragon” 九紋龍, after the nine dragons tattooed on his shoulders, arms, chest, and belly. It is likely that the cultural practice of full-body decorative tattoo in Japan has continued since the seventeenth or eighteenth century to the present day directly because of the popularity of this novel (called *Suiko den* in Japan). The responsibility lies with a painter named Katsushika Hokusai 葛飾北齋 (1760–1849) and a woodblock printing artist Utagawa Kuniyoshi 歌川国芳 (1798–1861). In illustrating various editions of the novel, these craftsmen gorgeously decorated more heroes with tattoos than those originally described as such in the novel. The illustrations in the Japanese editions of the novel fueled a tattoo craze in Japan (which, incidentally, might have helped fuel the current craze for tattoo in modern China, several centuries later). The link below is to an image of the Nine-Patterned Dragon of Shi Jin from an eighteenth-century Japanese woodblock illustrated version of the novel. <http://artofrezumi.tumblr.com/post/13301892145/utagawa-kuniyoshi>

One rarely read but important source of information of tattoo practice in China is the ninth-century miscellany *Youyang zazu* 酉陽雜俎 (*Miscellaneous Morsels from Youyang*), by Duan Chengshi 段成式 (c. 800–863), particularly because of the eleven entries in which this amateur ethnographer records in astoundingly meticulous fashion some of the pictorial and textual tattoos that he saw. These eleven entries reveal that people of various social ranks, even officials, were extensively tattooed with pictures or with literary texts or both. Duan was ever on the lookout for odd things in ordinary society, and he records not only tattoos that were commonly seen on the streets of cities in his own time, but he also tells of special visits he and his friends made to the homes of tattooed people to admire the body work in person. He describes the official reaction to some tattooed people, particularly ruffians who prowled the streets making trouble (some of whom were associated with the military), as violently negative; he mentions one government crackdown in which thirty tattooed men were beaten to death and their bodies exposed in public to discourage others from becoming tattooed.

The vivid picture that Duan paints of the streets of major Chinese cities such as Jingzhou and Chang'an is not seen elsewhere; mention of such subversive activities is not a topic of interest for most educated literati. For this reason, we owe a debt of gratitude to Duan Chengshi, who did not shirk from any subject, no matter how unsavory others might have found it. In fact, Duan's descriptions seem anything but negative; at times his descriptions are neutral and detached, but at others he openly acknowledges the artistry and beauty in the tattoo that he sees. Duan pricks the reader's imagination with these entries, particularly in cases like the man who holds a respectable official position, but under whose concealing robes lies a full-body tattoo of an undulating snake. When the man is drunk at parties, his friends convince him to disrobe and pretend to scare the entertainers with his tattoo. As Duan possibly intended, the reader cannot help but wonder if there were other officials like this man or if he was an anomaly

in his social class. Duan also tells us that he visited the home of a policeman to see his tattoos. The man disrobed and revealed a body entirely tattooed with poems by his favorite poet, Bai Juyi 白居易 (772–846). This is not the only example of literary text used as tattoo, but it is certainly the most tantalizingly unusual one.

The robed official's tattoos perhaps represented and expressed his hidden animal nature, which reminds us of one of the reasons the stigma was so strong in the first place among Han Chinese. Of a higher and presumably more acceptable social register, the policeman's second skin allowed him to identify with and honor his beloved poet. Other bearers of tattoos felt endowed with supernatural strength, like the man whose back was graced with a Buddhist deity; twice a month he would have his wife and daughter worship the deity and offer milky gruel to it, to ensure that he could continue to lift heavy weights. In other entries it appears that pictorial tattoos might have been considered effective apotropaic devices.

In a few entries, Duan describes the fine quality of the tattoos that he saw: "On his chest and belly appeared mountains, pavilions, parks, ponds and kiosks, grass and trees, and birds and animals. There was nothing that wasn't included. The tattoo was so fine that it was as if it had been painted on with repeated fine washes of color." He does not describe the techniques by which such complex figurative tattoos were created, but in another entry he outlines a simple means by which people could instantly be tattooed on the street. "In Jingzhou, during the *zhenyuan* era (785–805), there were tattoo vendors in the street. They had imprinting stamps into which they would press needles closely together into the shapes of all kinds of things, such as toads and scorpions, mortars and pestles, or whatever people wanted. Once they'd imprinted the skin (with this needle stamp), they would brush (the pricked area) with black lead. After the wound had healed, the tattoo was finer than that on the patterns from which the customer had originally ordered." It is clear that tattoo was readily and openly practiced during Duan's lifetime and that there was a high demand for it. It is possible that

the roadside customers were former criminals or soldiers, but it is also likely that there was a good deal of interest in tattoo among the general population and possibly even among the upper classes.

Tea in India

Philip A. Lutgendorf
Department of Asian and Slavic Languages and Literatures, University of Iowa, Iowa City, IA, USA

The story of how tea cultivation was brought to the South Asian subcontinent and gradually established there as a major industry (said to be contemporary India's second largest employer, after the railways) is notably marked by experimentation, innovation, and scientific and technological advances that were subsequently adopted by tea producers in other parts of the world. The initial impetus for this came from afar in the immense thirst for tea that developed among the population of the British Isles beginning in the late seventeenth century. Brewed with leaves imported from China, the beverage was at first a luxurious and medicinal privilege of aristocrats, but during the next century, as its import gradually increased and its price declined, it spread to the middle and eventually the working classes. By the end of the eighteenth century, tea, usually served with milk and heavily sweetened with sugar produced by slave labor in the Americas, had become a staple of British life.

The commercial entity most involved in this process was the East India Company, which had acquired virtual hegemony over the Indian subcontinent by the mid-eighteenth century. Using India as an entrepot in the China trade and opium cultivated there as an exchange commodity, the Company was able to ship tea profitably back to the motherland. Yet by the 1780s, its directors worried about the Chinese monopoly over this now-essential commodity, the cultivation and processing of which was treated as a state secret by the Qing imperial regime. In the nineteenth century, as Britain fought two Opium Wars to keep the tea trade profitable, they began investigating the possibility of its cultivation in the vast subcontinent under their control. Ingenious and clandestine attempts to smuggle plants and seeds out of China met with little success, as *Camellia sinensis* mostly failed to thrive under Indian conditions (Rose, 2010; Griffiths, 1967, pp. 42–50). But in December, 1834, a robust plant from the forests of Assam in northeast India was definitively identified, after nearly a decade of horticultural debate, as a broader-leafed variant of the Chinese plant (var. *assamica*) – a discovery promptly and portentously hailed by the Governor-General's recently appointed Tea Committee, as "...by far the most important and valuable that has ever been made on matters connected with the agricultural or commercial resources of this empire" (Griffiths, 1967, p. 41). An initial shipment of eight chests of its dried leaves, processed with the aid of Chinese informants, created a sensation on the London auction market in 1839 and precipitated a virtual tea rush, as investors envisioned a burgeoning industry in British-controlled lands (Fig. 1).

Yet conditions in Assam differed greatly from those in China, where tea had been produced for more than 1,500 years as a cottage industry by small growers who shared local and likewise small-scale processing facilities. Assam, which had come under Company control in 1826, was thickly forested and thinly populated. To produce tea on a scale sufficient to meet British demand would require the clearing of thousands of acres of jungle and the creation of large plantations

Tea in India, Fig. 1 A sign planted among tea bushes on an estate in northern West Bengal points, both literally and figuratively, toward the tea garden's mechanized hub, where the freshly picked leaves of *Camellia sinensis* var. *assamica* are processed into dried, black "CTC" tea (Photo by the author, December 2010)

(euphemistically called “gardens”) on the model of those that produced other cash crops elsewhere in the colonized world. Following the abolition of slavery in the British Empire in 1833 (extended to India a decade later), a workforce for these tracts was secured by importing hundreds of thousands of indentured laborers – mainly landless, impoverished people from central India, many of whom perished due to the unfamiliar climate, unhealthy living conditions, and harsh work regimen to which they were subjected (Moxham, 2003, pp. 127–189). Despite this and despite market conditions that did not always favor the new Assam product (a darker, black or fermented tea that only gradually won acceptance over the largely green Chinese varieties), Assam growers began realizing significant profits by the 1850s. Cultivation and harvests expanded dramatically in succeeding decades, and by 1888 India overtook China as the principal supplier of tea to the United Kingdom (Fig. 2).

Although most of it passed through the auction houses and port of Calcutta, growers and traders had little interest in selling it to Indians, who showed – even well into the twentieth century – similar disinterest in drinking it. Many who were drawn to the Independence struggle regarded it as an exploitative, imperialist product, but most Indians simply had no experience of it. That India is today not only one of the world's leading producers of tea (with a crop of roughly 1.2 billion kilograms in 2013) but also its single

biggest consumer (accounting for more than 80 % of its own crop) reflects a history in which technological and marketing innovation shares the spotlight with economic and political developments.

From the beginning, the large scale of tea cultivation in Assam, difficulties in securing labor, as well as the distinctive qualities of the local plant led owners to experiment with cultivation and manufacturing methods that differed from traditional Chinese practice. Since tea leaves must be processed rapidly after plucking, most gardens had their own factories, and efforts to mechanize these, with a view to reducing both manpower and processing time, began almost immediately. Many of the pioneer planters – who were once as romanticized in colonial narratives as they are now maligned in postcolonial histories – were amateur inventors who devised machines, some of which would eventually be patented and manufactured, to accelerate and standardize the three basic stages of leaf processing for black tea: initial withering or wilting, rolling (manipulation of the leaf to break down cellular structure and expedite the oxidation process – the latter often erroneously called “fermentation”), and drying. In place of the shallow baskets in which the Chinese withered small batches of leaves, Assam planters devised huge troughs lined with wire mesh, around which, in time, air was mechanically circulated at a controlled temperature and humidity

Tea in India, Fig. 2 A World War One-era newspaper ad (from an English-language daily in India) suggests the centrality of tea, produced by poorly paid colonial labor, in the British imperial and military project (Image courtesy of Urban History Documentation Archive, CSSSC Kolkata)

in a process that could require 12 hours or more (Fig. 3).

Hand rolling, another Chinese practice, was replaced by the 1870s by machines like the Nelson Roller, in which large batches of leaf were massaged for a fixed period between rotating metal plates and which “reduced by 75 % the time required for the hand-rolling process” (Griffiths, 1967, p. 493). For drying, the Chinese practice of pan firing in outsized woks was supplanted by the 1880s by drying machines, which were large ovens heated by coal – so that India’s coal reserves became as crucial to tea growers as they were to its railways and steel mills.

These technologies, largely in place by the end of the nineteenth century, contributed to enormously increased production. The 1880 crop of 43 million pounds was doubled less than a decade

later and then rose to 197 million pounds by 1900 (Moxham, 2003, p. 114; Griffiths, 1967, p. 128). Expanded acreage only partly accounted for this increase. Constant improvement in horticultural techniques (including the gradual elimination of introduced Chinese strains, which had initially been favored and had hybridized with the Assam variety, a process eventually recognized as undesirable) would see per-acre yields rise from 100 to 200 lb in the early decades of cultivation to 1,500 lb by the mid-twentieth century. Such improvements and the control of diseases and pests were initially the main concerns of a well-equipped Experimental Station financed by growers through the Indian Tea Association (ITA, established in 1881), which opened at Tocklai, Assam, in 1913 and thereafter reported on its research at the Association’s annual meetings (Detailed Report, 1914, p. iv).

Yield itself would eventually help drive renewed innovation, especially as India had to compete in international markets, after the 1880s, with other black tea industries in Ceylon (Sri Lanka) and Java. Bumper harvests worldwide coincided with decreased consumption during the First World War and the Great Depression of the 1930s, leaving Indian growers – even after ITA-mandated reductions in output – with an annual unsold surplus of more than a hundred million pounds of tea, which sparked interest in creating a domestic market for this export crop (Fig. 4).

This required innovative marketing, and in the largest such effort ever mounted on the subcontinent, the Indian Tea Market Expansion Board (ITMEB), established in 1936, began a massive campaign to convert the population to the tea habit through eye-catching advertising and signage, model tea shops in railway stations and bazaars, and traveling tea vans that demonstrated tea making and passed out tens of millions of free cups of the beverage (Fig. 5).

The ITMEB also borrowed the packaging and sales methods formerly used to promote tobacco, creating tiny one-pice packets on perforated chains that were sold for the smallest unit of currency and intended to appeal, once the habit had taken hold, to poor consumers as pay-per-use

Tea in India, Fig. 3 Tea leaves fill huge troughs in a multistory “withering house” on an estate in northern West Bengal. An overhead cable system is used to transport bags stuffed with leaves to the next stage of their processing (Photo by the author, December 2010)

Tea in India, Fig. 4 The cover of a Bengali-language brochure produced circa 1938 for the Eid festival by the Indian Tea Market Expansion Board shows the “journey of tea” from garden to middle-class couple, emphasizing the modern, industrial stages in its manufacture and transport (Image courtesy of the Urban History Documentation Archive, CSSSC Kolkata)

doses (Bhadra, 2005, pp. 19–26; Collingham, 2006, p. 187–208; Indian Tea, 1936–37). Somewhat hampered by the Second World War and the final phase of the Independence struggle, promotion continued after 1947, when British growers and packers began selling their businesses to Indian entrepreneurs and when the ITMEB became the Tea Board, a division of India’s Ministry of Commerce.

The gradual creation of a large domestic market eventually led to further technological

innovations to protect the industry’s profit margin, since most Indian consumers could not afford to pay the prices that tea fetched overseas. The basic machinery for tea processing had changed little since the late-nineteenth century, although a few estates experimented, beginning in the mid-1920s, with devices such as the Legg Cutter. Adapted from tobacco processing, this was used in humid areas such as the Dooars region of northern Bengal, where proper withering was difficult to achieve during monsoon

Tea in India, Fig. 5 An ITMEB poster from 1948 by commercial artist Annada Munshi, created as part of a campaign to encourage factory and mill owners to offer “tea breaks” to workers on the argument that it would improve their productivity (Image courtesy of the Urban History Documentation Archive, CSSSC Kolkata)

months. By slicing large, unwilted Assam leaves into tiny strips, the device accelerated oxidation, though many tasters did not favor the resultant product. By the mid-1960s, Legg Cut tea would be superseded by another and more widely adopted processing innovation.

In 1931, William McKertcher, Chairman of the Amgoorie Tea Estate in Assam, had invented a machine to crush, tear, and curl lightly withered leaves using steel rollers studded with sharp teeth. Dropped between two such rollers rotating at different speeds, leaves were torn into tiny fragments that oxidized rapidly. Tea produced by this process became known as CTC, as opposed to the rolled, full-leaf product that was now dubbed Orthodox. The CTC process

produced a tea of exceptionally strong liquor that held up well to copious amounts of milk and sugar – suiting Indian tastes – but, like most growers of his period, McKertcher still had the export market in mind, specifically the new American penchant for teabags that required just such a product. In any case, his machine was cumbersome, expensive, and difficult to clean, and its widespread adoption was delayed for nearly three decades (Dutta, 1992, pp. 126–129).

After Independence, India’s share of the international trade continued to decline, while its growing domestic market, so assiduously cultivated in previous decades, demanded a yet more affordable product. The ITA, recognizing that it had invested too heavily in horticulture and insufficiently in industrial capacity, appointed a Senior Research Engineer to its scientific staff at Tocklai in 1955. Thereafter, annual reports spoke excitedly of progress in the quest for continuous manufacture, in which all stages of tea processing would be fully mechanized. Attempts to develop harvesting machines to replace hundreds of thousands of mainly female tea pickers met with little success, in part because of the topography of Indian gardens. But in 1957, Tocklai introduced the McTear Rotorvane, named for its engineer-developer – an elaborate grinder to mash partly withered leaf into *maal* (Hindi for “raw product”) ready for rapid oxidation on a conveyer belt (Detailed Report, 1958 p. 107).

The most important breakthrough, however, came at the end of the decade, when Indian engineers in Calcutta (now Kolkata) redesigned McKertcher’s 1931 device as a sliding-block CTC machine. This machine was cheaper, more efficient, and more easily serviced because its heavy steel rollers could be slid in and out with relative ease (Fig. 6).

Its sharper steel rasps also led the machine’s acronym to be redefined (by those in the know) as cut, tear, and curl. Patented by the Small Tools Manufacturing Company but quickly pirated by others, the improved CTC machine gradually spread throughout Assam and Dooars gardens, and then far beyond. The device revolutionized the industry and finally made possible the vast

Tea in India, Fig. 6 An improved “sliding-block” CTC machine, circa 1965, produced by the Small Tools Manufacturing Company of Calcutta (Image courtesy of Anik Palchoudhuri)

Tea in India, Fig. 7 A streetside chai shop in north Kolkata that serves up a blend of water, rich buffalo milk, and CTC tea leaves, mildly spiced (at the customer’s request) with fresh ginger (Photo by the author, April 2011)

expansion of its Indian consumer base, for it inexpensively produced a strong-liquoring product that became beloved of Indian merchandisers and consumers since it also doubled

cuppage – the number of servings obtainable from a given weight of dry tea (Lutgendorf, 2012, pp. 21–24). Over the next four decades, CTC came to dominate the Indian industry,

Tea in India, Fig. 8 Conveyor belts move leaf fragments through successive “cuts” by CTC machines to large, rotating “googhy” drums in a tea factory in northern West Bengal (Photo by the author, December 2010)

comprising roughly 90 % of production by the beginning of the twenty-first century and becoming the obligatory ingredient in *chai*, the ubiquitous national beverage, produced by boiling tea particles in a mixture of water, milk, and sugar, occasionally with the addition of spices like ginger and cardamom (Fig. 7).

By contrast, the full-leaf and expensive Darjeeling Tea that is prized internationally, produced at higher elevations from a plant that is closer to the introduced Chinese strain and processed by the (similarly mechanized but less complex) Orthodox method, now accounts for only about 1 % of the Indian crop.

Today, in realization of the once-futuristic dream of continuous manufacture, CTC machines are generally used as one component in a largely automated production process (Fig. 8). Withered tea leaves fall through a chute into some variation on the Rotorvane (for initial crushing of the leaf) and then, after passing through three to four cuts between CTC rollers, tumble through googhys (huge rotating aluminum drums that give the leaf fragments a characteristic curl to produce a granular

Tea in India, Fig. 9 An automated and coal-fired drying machine for “flash-firing” CTC tea particles at high temperature; the flues on the left are used to extract “tea waste” (Photo by the author, December 2010)

Tea in India, Fig. 10 The author contemplates a (possibly) lifetime supply of just-dried CTC granules, awaiting packing in the warehouse of a tea factory in northern West Bengal (Photo by the author, December 2010)

product). Then they are moved along continuous bed fermentation belts, to finally drop into giant ovens that flash-fire them at 225° Fahrenheit, halting oxidation and removing all but 3 % of their moisture, while also sucking out, through huge ducts, the sawdust-like chaff of stem fragments (Fig. 9).

Sorting machines then sift out various grades of tea, from larger broken orange pekoe leaf fragments to the finest dusts (the latter often highly valued in Indian markets), which are then packed in moisture-proof bales or containers. The whole process of production – from picking to packing – generally takes less than 18 h, and its end product may go up for auction in Guwahati or Kolkata within days or weeks. Speed of processing and delivery, no less than mechanized efficiency, is important to an industry and consumer base that prizes freshness in tea and that maintains, even for cheaper grades, surprisingly high standards of connoisseurship (Fig. 10).

As a postscript, it may be noted that the chaff expelled by modern drying machines – so-called tea waste – is actually not wasted at all. It is largely shipped abroad for the manufacture of

instant and flavored teas, products that (to the wonder and amusement of Indian tea industry insiders) are now valued by consumers in certain countries of the postindustrial West.

Tea and Tea-Drinking Customs

There are three different stages of tea drinking in the history of Japanese society. Tea – as a form of beverage – and the social custom of drinking it, and, possibly, even the plant *Camellia sinensis* itself, were first introduced in the late ninth century by Buddhist monks who had made a pilgrimage to Tang-era China. As it was a precious commodity, its consumption was limited to the inner circle of the imperial court, and it was employed mainly for religious ceremonies (Murai, 1989; Shimaō, 2014).

The second stage of the custom of tea drinking in Japanese society was the end of the twelfth century. Eisai, a Buddhist monk who had made a pilgrimage to Song China, introduced a new type of tea – *matcha*, which is ground or powdered green tea – and a new method of preparing it (Hashimoto, 2013).

Finally, a new method of making tea – steeped leaf tea – was introduced from Ming China and a new manufacturing technique was invented in Uji. This type of tea became a popular commodity in the urban areas by the mid-seventeenth century (Yoshimura & Wakahara, 1984).

The Historical Developments of Tea Cultures

Drinking Tea at the Imperial Court

When the custom of drinking tea was first introduced to Japan, the imperial court initially

accepted it as part of religious ceremonies, such as the seasonal sutra reading rituals held every spring and autumn at the imperial court (*Kinomidokkyo*) (Murai, 1979, 1989; Uruma, 2001). However, tea itself was not central to this religious ceremony. Rather, tea was offered after the seasonal mass to relieve the fatigue of the priests in attendance on the day of the ceremonies (Murai, 1979).

It is commonly understood that the tea during this period was made from a tea brick in which the tea leaves were steamed, packed in moulds, pressed into block forms, and then toasted. The brick tea was then grounded into powder, decocted, and flavored with salt and spices such as raw ginger and arrowroot before serving (Murai, 1979; Shimaō, 2013). The beverage was served to reward the priests at the annual mass. The use of tea during this period was medicinal rather than epicurean (Murai, 1979; Shimaō, 2013).

When tea was first introduced to the imperial court in the late ninth century, Emperor Saga appears to have ordered the cultivation of the plant *Camellia sinensis* to meet the demand of the semiannual use at the imperial court, so tea was an entirely private and strictly limited phenomenon (Hashimoto, 1999). In fact, neither the production nor consumption of tea seemed to have been a part of the lives of courtiers even though a small amount of tea seemed to have been continuously cultivated on the premises of the imperial court and at some Buddhist temples (Murai, 1979).

Powdered Green Tea and Zen Monasteries

Even after the new form of powdered green tea and a new tea-making method were transmitted to Japan from China by a Buddhist monk at the end of the twelfth century, access to tea was still limited to the small circle of the ruling class, namely, the members of the imperial court and religious institutions, and its purpose remained ceremonial. Only a modest amount of tea was cultivated on the premises of temples and shrines.

Powdered green tea became essential to the monastic life of Zen monks. The tea was made and served on various occasions during the rituals

and annual ceremonies outlined in the *Shingi* (*Qinggui*) – the written codes of conduct regulating all aspects of monastic existence – from the form of organization to the conduct of daily life, including rituals and ceremonies (Hashimoto, 2013). Through the implementation of *Shingi* at various temples, tea was an essential part of the life of Zen monasteries (Shimao, 2014).

The custom of drinking powdered green tea has been strongly associated with the Zen Buddhist practices since Eisai introduced it, and he has long been understood as the founder of one of the Zen sects, Rinzai. However, as the work of religious historians since the 1970s has shown, the Buddhist orthodoxy in medieval Japan was *Kenmitsu* – the coexistence of exoteric and esoteric Buddhism – and the Rinzai sect in its early stages was a consolidation of Zen and esoteric Buddhism (Hashimoto, 2013). Moreover, the cultivation of the plant and manufacturing of tea was not limited to Zen temples. On the contrary, the tea plants were first cultivated on the premises of exoteric-esoteric Buddhist temples such as Kozanji of Mount Togano-o (Hashimoto, 1999). In other words, as Hashimoto makes clear, the custom of drinking powdered green tea was not exclusive to the Zen monasteries. Thus, the custom of tea drinking was first introduced to the exoteric-esoteric Buddhist temples and then emulated by members of the secular world (Hashimoto, 2013).

Playing with Tea

Tea was still a luxury good and a favored gift, because the supply was very limited. Temples in Kyoto and Nara were the only places where tea was cultivated and manufactured, and it was distributed only through personal channels (Hashimoto, 1999, 2013). However, with the rise of military power and the relocation of the political center to Kamakura in the east, tea drinking and the cultivation of tea spread to the temples in Kamakura through the circulation of goods and people between the capital and the new political center.

With the expansion of tea cultivation, although its distribution was still limited and

private, the custom of drinking tea finally spread outside the religious institutions and developed into a form of entertainment: tea matches (*tōcha*) were played by the military elite, the emerging new social power, by the mid-fourteenth century (Murai, 1979). Although the cultivation and manufacturing of tea remained private and its distribution was made only through personal channels, tea cultivation was gradually transmitted to religious institutions in Kamakura and then to the wider society (Hashimoto, 2013; Murai, 1979).

Gathering for Tea in Shogun's Audience Hall (Shoin)

In the fifteenth century, during the rule of the Ashikaga shoguns, the political center was again relocated to Kyoto. Tea drinking now developed into a more elaborate social practice that required more refined space and aesthetics, as it was performed at the Shogun's residence. The audience hall was decorated with a number of *karamono*, the objects which were brought back from China and beyond by Buddhist monks to Japan, and turned into a space where the authority of the ruler was displayed. Additionally, elaborate rituals performed at the Shogun's residence developed a refined style called *karamono suki*, producing both art connoisseurs serving the shoguns as cultural advisors (*Dōbō*) and written instructions for decorating the hall, such as *Kundaikansōchōki*.

Tea Gathering as Political Theater

Eventually, by the sixteenth century, the custom of drinking tea had developed into a form of art, which we now identify as *chanoyu*, or the Japanese tea ceremony. By the time of Oda Nobunaga and Toyotomi Hideyoshi, tea gatherings served as opportunities for political theater for military leaders. As a result, the production of tea was encouraged and patronized by the military leaders to ensure both the quantity and quality of the supply. With the increase in demand for a stable supply of tea, new regions emerged as tea plantations, such as Uji, a village near Kyoto (Yoshimura & Wakahara, 1984).

Gathering for Tea in the Cities

The practice of tea gathering was not exclusive to military leaders. Wealthy town commoners in prosperous cities such as Kyoto, Nara, and Sakai also began practicing the elaborated tea-drinking ritual in the fifteenth and sixteenth centuries (Murai, 1979). They themselves developed an individual style of *chanoyu* that differed from the practices of the Ashikaga Shogun.

A New Invention: Steeped Leaf Tea

By the mid-seventeenth century, another type of tea – steeped leaf tea – became more popular and began to circulate in the urban markets. This type of tea is called *sencha*, the beverage made by steeping tea leaves that are dried and roasted in metal kettles in hot water. The legend is that the Chinese monk Yunyuan Longqi, who established the Manpuku-ji temple on Mount Ōbaku, introduced this new type of tea from Ming China. However, tea plantations in Kyushu had a long history of producing roasted tea and claim that their manufacturing method was introduced from Ming China in the fifteenth century during Hideyoshi's invasion of Korea (Yoshimura & Wakahara, 1984).

Tea producers in Uji invented a new tea-manufacturing method, which was rapidly transmitted to tea plantations outside the area so that *sencha* became the most popular beverage among the city dwellers (Yoshimura & Wakahara, 1984). Consequently, a tea-manufacturing industry developed during this period, producing tea that was ever more accessible though tea as a commodity was still limited to the urban population.

Tea in the Rural Areas

Before the transmission of the custom of drinking tea from China, and for villagers more generally, decoctions of various herbs like persimmon leaves appear to have been the favored beverage for both the elite and common folk alike (Uruma, 2001). Furthermore, villagers are known to have been drinking roasted tea, or *bancha*, since the medieval period. This beverage was made from *Camellia sinensis* that was privately cultivated or collected from mountain areas (mountain tea) but

processed differently from what the elite consumed (Hashimoto, 2013; Nakamura, 2013). There remains a debate as to whether or not *Camellia sinensis* is native to Japan, though the majority of historians agree that it was imported from China at some time in history (Terada, 2013).

In the Modern Period

The production of green tea was encouraged by military rulers like the Shogunate and other lords during the Tokugawa period. However, the system of tea production has changed dramatically since the 1850s. With the opening of Japanese ports to foreign trade and the fall of the Tokugawa Shogunate that followed, tea producers and manufacturers changed their business structure to fit the new world of a market-oriented economy. The leaf tea processed using the Uji method became one of the key commodities that were viable for export.

By the early 1980s, 80 % of green tea in the Japanese market was manufactured using the Uji method noted above (Yoshimura & Wakahara, 1984). While Uji-method green tea has become a popular everyday beverage in contemporary Japan, the drinking practice of *matcha* (powdered green tea) is viewed as a cultural practice that is deeply associated with Japanese tradition.

Technology

Arnold Pacey

The development of technology has usually been socially determined, changing in direction as different social formations have emerged. For example, there are important distinctions to be made between, first, small communities of farmers or dispersed groups of hunters with technologies outstanding chiefly for their adaptation to local *environments*; second, the larger kingdoms and empires, whose technology tended to be *engineering-centered*; and third, trading communities and merchants or entrepreneurs with *production-centered* technologies.

An initial problem in discussing technologies of the first kind is nomenclature. Weiner, who has discussed the remarkable protective clothing developed by the Inuit for life in the Arctic, has described these people as “the great pioneers of microclimatological bioengineering.”

This tribute to the control of body heat loss achieved by Inuit clothing is well deserved but places the skills of Arctic people within the wrong frame of reference. Their technology was environment-centered, not engineering-centered. On the one hand, they were adapting to a very demanding environment; on the other, they were making very efficient use of environmental resources. Thus, the animals hunted for meat were also a source of oil for lamps, bone for making needles and other tools, and the skins, intestines, and fibers from which clothing was made.

Archaeological evidence suggests that the invention of tailored skin clothing adequate to enable people to winter in the Arctic was accomplished in Siberia around 2000 B.C.E. After that, it was several centuries before oil lamps, houses built of snow, and dog sleds were developed by the people of the Dorset Culture, based on Baffin Island. Later still, improved boats and harpoons were developed by the Alaskan Inuit.

All these inventions, quite clearly, were the work of small, dispersed groups without centralized organization, and all were responses to an exacting environment. Perhaps what we ought also to remember is that for the Inuit, as for most non-Western peoples, the environment was endowed with personal and spiritual meanings, and with magical qualities. It was not merely the object of detached, if concerned, analysis that it has become for most Westerners. Thus, their technology was based on an organic world view.

The same points can be made about peoples inhabiting other environments, such as rainforests, deserts, steppes, or coastal and island situations. The efficiency with which resources were used by such people is illustrated by the estimate that in A.D. 1500 the Amazon basin supported a somewhat larger population than it did in 1990, yet without the extent of destruction of forest and fishery resources now taking place. Fruits, nuts, leaves, seeds, and roots were gathered for use as food and medicine. Fish and animals were caught, often using poison tipped spears, but with less ecological disturbance.

In some rainforests, notably in Central America as well as in Asia and Africa, people developed a form of agriculture in which a great variety of

crops was raised while extensive tree cover was retained. Cereals such as corn in the Americas or rice in Southeast Asia were grown in forest glades with shade tolerant vegetables under trees. Those trees that were left unfelled or were newly planted would be selected according to whether they produced fruit, nuts, timber, fodder, or *materia medica*. Thus, an artificial rainforest was formed in a system often referred to as forest farming, forest inter-culture, layered gardening or, more recently, agroforestry. The key point – whatever the name – is that there would always be tree cover, and usually other vegetation, to protect the soil from erosion and to retain plant nutrients. By contrast, where rainforest is cleared for conventional western style agriculture, soils become degraded very rapidly.

In Africa, rainforest crop production became widespread only after the banana and Asian yam were introduced on the east coast by Indonesian traders and colonists around A.D. 400–500. In quite a short space of time, these crops were adopted by many gardeners across the continent, enabling populations in forested areas to increase considerably. In Central America, archaeologists have now shown that the Maya culture used forest farming with high yielding nut trees and manioc (cassava) as major crops around A.D. 600–900.

Other environment-centered technologies were those of people living in hot, dry, semidesert conditions who evolved sophisticated water conservation techniques. Some of these made use of small structures, such as check dams in gullies and spreader dikes on flatter ground – for example, in northern Mexico and Arizona – or else stone lines on contours (in the African Sahel). Others practiced the careful planning of fields in relation to rainwater catchment areas, and the construction of bunds to channel water and hold it on the land. Among the most elaborate ► [rainwater harvesting](#) systems of this kind were those of Nabataean farmers in the Negev Desert in Israel from about 200 B.C.E., and comparable systems in Morocco and elsewhere in North Africa. Small dams, river diversions, and the Persian ► [qanat](#) (wells linked by a tunnel) were other means of providing irrigation water to crops on a small scale.

Consideration of environment-centered techniques such as these offers a distinct perspective on early technology quite unlike the conventional view based on the materials from which tools were made, namely, stone, bronze, and iron. That view seeks to discover a pattern of tool use and metal-working skill common to all human societies, and ignores the environmental particularism emphasized here. It parallels the modern assumption that the principles of technology are independent of cultural values and underestimates the different ways in which human societies explored the varying surroundings in which they lived. By contrast, a perspective based on environmental adaptation allows one to recognize the extraordinary sophistication of some peoples who nominally remained in the “Stone Age” even in the early twentieth century, including the Inuit and some rainforest communities.

Viewed from another angle, however, the Neolithic period in the later Stone Age does seem to have been a time of particularly important innovation, at least for western Asia. It is associated with the first domestication of crops and livestock, and hence the invention of agriculture, probably associated with the earliest use of some of the water conservation techniques previously discussed. Complementing these innovations were others, such as pottery (and soon after, the potter’s wheel), grain milling, tool-making, and textiles (with the looms on which they were woven). Many of these innovations relate to the domestic sphere of life, and it is likely, therefore, that many of the inventors concerned were women.

It would be a mistake, however, to assume that the invention of agriculture, the domestication of plants, and the appearance of pottery or textiles were unique events, each occurring only once in human history, in one part of Asia and then diffusing to other regions. Independent inventions undoubtedly occurred, just as different crops were domesticated in various places and at different times. For example, about 1500 B.C.E., corn (i.e., maize) and pottery were both known in Mexico, but not in Peru, where beans and peppers were cultivated. Thus, the two cultures may have developed agriculture independently of one

another. Moreover, some plants were still being newly domesticated in the twentieth century, for one reaction to deforestation in Africa has been to cultivate a number of fruits and vegetables that people had collected from the wild until the loss of forest cover threatened their existence. Reports from Kenya show how modern gardeners, usually women, have selected from wild varieties and have produced strains adapted for garden conditions.

Engineering-centered technologies developed in a very different context. They were characteristic mainly of kingdoms or empires whose labor resources and administration made large scale construction works possible. One view of the origins of engineering is that once agriculture was established, irrigation became necessary in many of the warm, dry countries of western and southern Asia to produce sufficient food for growing populations. The dams and canal systems necessary for irrigation could not have been constructed, it is argued, without recruiting a large labor force, and that in turn could not have been done except in centrally organized kingdoms. In this view, the need for irrigation canals and other hydraulic works dictated the formation of centralized government administrations with the coercive power and management skills needed to organize large scale construction works.

This theory about how hydraulic civilizations evolved does not apply everywhere, however, since empirical evidence shows that in many areas where irrigation was practiced, farmers did the essential earth moving and engineering work themselves, or with their neighbors through local systems of cooperation, but without central organization. This seems to be true for rice culture in China, according to Francesca Bray. Some of the biggest centrally organized engineering schemes prior to A.D. 605, involving thousands of laborers, were not for irrigation but for construction of transport canals for carrying grain to the capital. However, flood control and irrigation in north China did depend on large scale works, so the evidence is not clear cut.

In Mesopotamia and Egypt, much early irrigation was also on a small scale, dependent on manually operated water raising devices such as

the *shaduf*. The type of crops grown and the seasons of cultivation meant that water requirements in early agriculture were much less than after the agricultural revolution of the Islamic period (after A.D. 700), when crops that demanded more water (including rice) were more widely grown. In Mesopotamia, large scale works were needed at an early date, but in most places it is hard to argue that the requirements of hydraulic management were sufficiently exacting to determine the development of centrally organized states. On the contrary, the prior existence of centralized political power made possible a wide range of construction programs that included fortifications, monuments, and temples, as well as hydraulic works, and it is impossible to say which kind of engineering came first. One of the earliest sites to provide evidence is Jericho, where defensive walls, but also big water tanks, have been found dating from before 6000 B.C.E. The pyramids of Egypt were among the largest construction projects ever conceived when they were begun about 2600 B.C.E. But a comparable amount of labor may have gone into embankments and canals built at about the same time for flood control and irrigation by the Sumerians in Mesopotamia. Thus, the evidence does not give a clear picture of hydraulic requirements, rather than other construction works, forcing the pace in either administration or engineering.

That brings us to a second hypothesis about how engineering-centered technologies evolved, suggested by Lewis Mumford and some like-minded commentators. This is the view that such technologies were related to the invention of institutionalized warfare. In early societies, conflicts were sometimes wantonly violent, but some groups had customs that enabled one side to signal a surrender before serious injuries were inflicted. Among a few isolated peoples in Africa and Oceania, conflicts between communities were still like this until recently, and observers note that, if somebody was killed, the combatants were so shocked that fighting immediately stopped. A ceremonial burying of spears and an exchange of cattle or captives would then settle outstanding issues.

Organized, lethal warfare had to be invented, perhaps during the Neolithic period, and possibly following the invention of agriculture, since agriculture made possible denser populations within which tensions could be greater. Also, agriculture produced the economic surplus needed to pay for arms and fortifications. The suggestion is that military institutions evolved from about this time and provided a model of how large bodies of men could be recruited, disciplined, and supervised while constructing fortifications, pyramids or hydraulic works. Many instances can be quoted of the administration of hydraulic installations based on military routines. In later times, at Marv in northern Iran, a water storage dam below the city was looked after by 400 “guards” who minutely regulated and recorded all outflows of water. The head of the water office had more authority than the local police chief, and when repairs to the dam or canals were necessary or when new works were needed, he could call up 10,000 people to do the work.

The development of warfare provided much other stimulus to engineering-centered technology. Mechanized fighting may be said to have begun with the clumsy, four-wheeled Sumerian chariot of about 2400 B.C.E. The Hittites, whose empire overlapped Asia Minor and Syria, invented some of the first effective siege engines around 1600 B.C.E. and introduced the first iron weapons soon after. Horses were initially used mainly for drawing chariots, their full potential for warfare only emerging much later with the invention of the stirrup and its associated harness. This freed the rider’s arms to use weapons while he remained securely in the saddle.

The most famous of military inventions was, of course, ► [gunpowder](#), known by A.D. 900, used in rockets by about 1100, and in guns before 1288. These inventions, developed within Chinese military institutions, were stimulated by earlier Indian discoveries about the chemical behavior of saltpeter, and by the use of incendiary weapons for naval warfare in Southeast Asia. The latter often depended on petroleum, obtained from surface oil seepages on the island of Sumatra. Although guns evolved more rapidly in Europe after 1300, China was the

source of many ideas for gunpowder siege weapons used in the Arab world, and there were transfers of Chinese firearms technology to Korea and Thailand.

Considerable resources were needed for manufacture of the heavy cannons that had become widespread by 1500, and only the larger Asian empires could afford them in any number – but those that could were then able to expand their territory and consolidate their power. In India, the Mughal Empire’s arsenals and gun-casting capability were important for its expansion between 1526 and 1700. In Persia also the new technology had a centralizing, consolidating influence during the reign of Shah Abbas (1587–1627), though his empire depended less on guns than did the powerful Ottoman or Turkish Empire, an exporter of guns and know-how. Given that most cannon were cast in bronze, McNeill has called this period a “second bronze age”, referring to “gunpowder empires” not only in connection with Turkish, Persian, and Mughal rule, but also in relation to China and the Russian Empire in Asia.

The ships used in naval warfare and trade in Southeast Asia were of sewn construction, with rattan fiber holding together carefully fitted timbers in a flexible hull suited to landing on sandy beaches. They usually had outriggers and tripod masts to support sails, and regularly crossed the Indian Ocean. The Chinese, meanwhile, were building larger ships whose wooden hulls were held together with iron nails and had watertight bulkheads. China was also developing inland water transport on a large scale. The canals had ramps and spillways for moving boats between one level and another, but also incorporated the first pound locks and lock gates, introduced in A.D. 983 (a precisely dated invention).

One Western bias in understanding technology is a tendency to focus on the wheel and machines using wheels. But wheels did not always mean progress. Wheeled vehicles were used in the north and west of Africa around 500 B.C.E., regularly crossing the Sahara Desert. Yet they went out of use later when the camel was introduced, because camels provided much more efficient means of transport in a region with sandy deserts

and no paved roads. For parallel reasons, wheeled vehicles were not much used in southern Asia. In Central America, rollers and wheeled toys have been found, but in a region where there were not animals capable of pulling carts, no purpose could be served by developing such devices.

The potter's wheel (and later lathes working on similar principles) were probably the first machines, around 3000 B.C.E., to use the wheel. Much later, a basic water powered corn mill evolved, with a vertical axle and propeller like blades below the millstones. One view is that this was a Greek invention made about the time of Alexander the Great. Another view, however, is that it arose out of the Hittite tradition of engineering which had earlier pioneered so much military equipment. After the Hittite empire collapsed around 1200 B.C.E., some aspects of its culture survived in Syria, and itinerant craftsmen perhaps reached Mesopotamia and Iran. It was probably in one of these countries that water mills originated. Since the same type of mill appeared in China not long afterwards, one might reasonably look for its origins close to trade routes with China. As for the introduction of the mill into Greece, this could be a by-product of Alexander's expedition through Iran to the Indus River in 330–323 B.C.E.

Some thousand years later, Iran was certainly where an early type of windmill was invented. It worked in much the same way as the vertical axle water mill, though mounted in a tower with vents in the walls to catch the wind.

Mumford sees these inventions as part of the tradition of innovation stemming from small dispersed communities rather than from centrally organized states. However, at Baghdad, which had about one million inhabitants in A.D. 1000, corn milling was carried out by a series of floating mills on the Tigris River which operated continuously, night and day. The water wheels were of the later undershot type, driving millstones through wooden gears. Other uses of water power in Iraq and Iran by A.D. 1000 were in sugar cane crushing mills, fulling mills, and mills for preparing the pulp for papermaking. Paper manufacturing had been introduced at Baghdad in A.D. 794, probably with the help of

Chinese workmen, and pulping was water powered from about A.D. 950.

In all these instances, it would seem, we are no longer dealing either with the environment-centered technology of dispersed communities, nor with the labor intensive engineering of powerful centralized states. Rather, we are seeing the emergence of production-centered technologies in expanding industries. An even more striking example can be cited from northern China, associated with the use of blast furnaces for iron production. Methods of achieving high temperatures in furnaces were highly developed in China's porcelain industry as well as in metal smelting. Chinese iron masters had pioneered blast furnaces capable of melting large batches of metal, and output rose steadily to a peak in A.D. 1078. Moreover, the furnaces were owned and run by independent entrepreneurs whose market oriented, proto-capitalist operations are seen by McNeill as marking a turning point in world history.

More evidence that technology in China was moving into a new phase is provided by the great flowering of mechanical devices that were introduced there in the three or four centuries prior to 1250. They included spinning wheels, silk winding machines, and most striking of all, water-powered mills for spinning and winding thread of a local type comparable to linen. Some improvements in textile technology were due to women innovators, and many businesses were run in an independent, entrepreneurial style.

By contrast, much manufacturing in the major Asian empires was directed toward meeting state requirements for armaments, or the needs of royal palaces for luxury textiles, porcelain, and furniture. The most characteristic unit of production was the royal factory or *karkhana* in Mughal India, or the specialist porcelain factory or arsenal in China. At one time, 4,000 silk workers were employed in karkhanas in Delhi. Some may have been conscripted, and the factories were run in rather the same way as the labor intensive, state-run engineering works mentioned previously. Such factories were highly successful in meeting government requirements for arms or the court's demand for luxury goods, but could not respond readily to a varying market demand.

Production for purposes of trade, and especially for export, flourished most markedly where merchants and other entrepreneurs could function independently. By 1700, India had become the world's greatest exporter of textiles, sending its cotton cloth to Europe, Africa, and many destinations in Asia. Both Indian and foreign merchants were involved, sometimes financed by the many Parsi and Gujarati bankers to be found in ports such as Surat.

It should not be thought, though, that proto-capitalist industrial organization was always favorable to the use of machines, water powered or otherwise. The high quality of Indian textiles was achieved by painstaking handwork and a very fine division of labor. British observers noted that cotton cloth would sometimes be worked on by four people for every one employed on the same tasks in Europe. Thus, the remarkably fine muslin produced in Bengal was the result of many detailed processes which would be simplified and reduced to a single operation in the West.

Indian cloth was also noted for the fastness and brilliance of the colors with which it was dyed, mostly using vegetable dyes, such as indigo and madder. However, some inorganic substances were also needed as mordants, and this gave rise to a significant chemical industry. For example, the alum used in madder dyeing was produced in Rajasthan by processing broken shale tipped as waste around copper mines. The shale was steeped in water. Aluminum compounds were separated from copper salts by differential crystallization. Then a reaction with saltpeter produced the alum. These chemical processes were operated on a substantial scale but using labor intensive methods and minimal equipment. Merchants and banks had ample funds to invest in the textile trade, but because wages were low, there was little advantage in financing better production equipment. Instead, most of the capital available was put into building ships to carry exported cloth. Thus, Indian shipbuilding developed to a very high level in the eighteenth century. Ships were built for Indian merchants and foreign traders, and from 1800 for

the British navy. Meanwhile, cotton cloth, dye-stuffs, and chemicals continued to be produced by laborious manual techniques.

Similarly in China, there were many flourishing industries, often organized on proto-capitalist lines, but the interest in mechanization evident before 1300 was not sustained, and indeed, some machines went out of use. Silks, porcelain, and cotton goods were produced in quantity, but mainly by labor intensive methods in an economy where wages were tending to fall. But, as in India, the production technologies involved are of considerable interest. Moreover, they are quite distinct from the environment-centered and engineering technologies discussed earlier. It is of particular relevance to observe that printing evolved as a production technology in China, and by 1600 had export markets in Korea and Japan. But the content of the books being printed was dominated by the literary interests of the bureaucrats who served the imperial government. Thus, relatively few books were of significance for the dissemination of technical information. It is worth recalling, though, that the first known printed book, the *Diamond Sūtra*, an extract from the Buddhist scriptures, dates from A.D. 868, and that by the eleventh century a few books on agriculture were being printed. In A.D. 1044, Zeng Gongliang published the *Wujing zongyao* (Collection of Military Techniques) that quoted the formula for a weak [gunpowder](#) mixture, and in 1313 a remarkable work appeared – *Nong Shu* (Treatise on Agriculture) by Wang Zhen – which, among other things, described water powered spinning mills.

But whatever limited writings there were on technical subjects, either in Islamic manuscripts or Chinese printed books, technology depended far more on knowledge, skill, and technique passed from one craft worker to another through processes of observation, personal contact, and apprenticeship. Nonverbal habits of thought and of getting the “feel” for how a process should work were undoubtedly central for innovation and learning.

Nonverbal communication, often in the form of a visual or experimental dialogue, was also the

means whereby techniques were passed from one community or culture to another. Confronted with an unfamiliar product or process, a craft worker would not always copy it directly, but would “question” it to try and work out how the same result might be achieved by more familiar means, or how it might be reinterpreted to suit his or her community’s culture or resources. Moreover, this dialogue or questioning approach could at times prompt entirely new lines of thought or innovation. For example, between the sixth and tenth centuries A.D., the Chinese picked up ideas from India and Persia about chemistry, dyestuffs, textile printing, windmills, suspension bridges, and other matters. These were developed in entirely new ways as a result of being questioned and reinterpreted rather than being copied, and so contributed to some of the best known of Chinese inventions, including gunpowder and printing.

Between 1100 and 1800, and especially after their voyages of discovery began around 1450, Europeans were continually picking up ideas from other cultures: about water clock mechanisms, chemistry, cooking, and glassmaking from Islamic sources; about gunpowder, firearms, printing, and porcelain manufacture from China; and about metallurgy, cotton textiles, and dyestuffs from India. Few of these techniques were directly copied in any detail, but they became part of a dialogue in which Westerners did most of the questioning and learning – and in which they reinterpreted many techniques in terms of the Western enthusiasm for machines and mechanization.

This source of stimulus contributed significantly to the technology of the European industrial revolution, but that in turn brought a change in attitudes and relationships. A sense of technological superiority coincided with a tendency to use non-Western countries as markets for factory made goods and as sources of raw materials. Local manufactures in many parts of the non-Western world therefore declined. One striking feature of the late twentieth century has been a new openness in the West for dialogue with the environment-centered technologies practiced in the rest of the world. But, again, Westerners

are reinterpreting everything they learn in terms of their own outlook, discarding the organic and holistic world views of other peoples and fitting everything into an analytical, scientific frame of reference. Thus, Inuit technology has been discussed in terms of “ice alloys” and “bioengineering” whilst indigenous rainforest technologies are being reinvented as “ethnobotany” and “agroforestry”.

Technology and Culture

Claude Alvares

General accounts of the history of science and technology (or, more narrowly, of inventions) are scarce. The few that are available are also of fairly recent origin: obviously, the idea of a history of science (where science has been identified with Galilean science) and technology (identified with industrial technology) could not have appeared much earlier than this century. Not many people even know that the word "scientist" was first used by William Whewell in 1833.

Also, most available histories have remained the work of western scholars. This has not been an entirely happy circumstance. On the contrary, it has afflicted these histories with certain methodological and other infirmities which have had the effect of reducing them to mythological works. This is especially so when they are studied with regard to aspects of the history of science, technology, and medicine in the non-Western world.

One of the first is a history of technology and engineering written by Dutch historian Forbes. Forbes's work appeared in 1950 under the title *Man the Maker*. In it, he conceded that technology was the work of humankind as a whole, and that "no part of the world can claim to be more innately gifted than any other part." A few years thereafter, Forbes produced his rich and prodigiously detailed *Studies in Ancient Technology* which set out a remarkable description of the different technologies of Asia, Africa, pre-Colombian America, and Europe. However, it is in *The Conquest of Nature* that his Eurocentric assumptions came to the fore: in that work (as the title itself indicates), Forbes went on to subsume the technological experience of people from diverse cultures under a philosophical anthropology that was unmistakably Western, if not Biblical – the domination of nature myth originating in Genesis. And after a discussion about the grievous consequences of a seriously flawed

modern technology, he ended his book promising redemption from the technological genie through the Christian event of Easter. How does one prescribe a text like this to Hindu, Chinese, or Arab readers?

Another influential work of about the same period is *A History of Western Technology* by a German scholar, Friedrich Klemm. In it, Klemm provided a picture of technological development in the West in which non-Western ideas and inventions had no hand at all. The English translation which appeared in 1959 barely mentions Joseph Needham's work on China in the bibliography. Klemm could not have substantiated his interpretation of Western technological development unless he consciously played down non-Western technology. In fact, the only quote on Chinese technology in Klemm's book is from the *Guan yin zi*, the work of a Daoist mystic of the eighth century AD: Klemm used it to prove why the alleged religiously colored oriental rejection of the world in China could not have provided a stimulus for the emergence of science and technology in that country.

This distorting Eurocentric perspective continued to hold sway even over the more standard (five volume) *A History of Technology* edited by Charles Singer, Holmyard and Hall. The first volume of this work appeared in the same year as Joseph Needham's *Science and Civilisation in China*, and the editors themselves acknowledged that up to the period of the Middle Ages in Europe, China had the most sophisticated fund of technological expertise. Three of the Singer volumes dealt with preindustrial technology, where logically China (and India) should have been given major space and Western technological development would have appeared in proper perspective in the nature of an appendix. However, Chinese, Indian, and other technologies were ignored and Western technology made the focus of the exercise.

In addition to manifesting such ignorance of non-Western science and technology, these histories suffered from another methodological limitation: they restricted themselves to a record of artifacts and machines disembodied from the latter's social and cultural contexts. The problem

was eventually recognized by some Western scholars themselves.

These histories are evidence that the western scholars associated with them proved incapable of stepping out of their cultural cages, either knowingly or involuntarily. Either way, this eroded the credibility of their work as it exhibited both their lack of objectivity and their general incompetence when called upon to deal with societies other than theirs.

They show that our dominant descriptive and evaluatory ideas of technology and culture both in the Western and non-Western world have been formulated over the past couple of centuries with reference to the West's experience of these phenomena. Concepts and categories reflected from a limited area of human experience have been indiscriminately used to explain and assess the rest of the world.

New frameworks are therefore inevitable. We are in the posttraditional, postcolonial, and post-modern age. But unless the outmoded intellectual environment that engendered this subjective and tunnel-visioned output is rigorously dissected, analyzed, and then jettisoned, the new frameworks needed for the alternative histories and encyclopaedias intending to take their place are in danger of turning into copies of the old.

There are two preliminary aspects of this intellectual mal-development that need elucidation. First, there is the perception of humankind as *homo faber*, a tool-making animal, which is basically a reflection of fairly recent Western experience with the machine. Fascinated by the bewildering profusion of tools and machines, Western historians began to look at the ability to produce these as a special field with its own history and set out to create a distinct species of man in the image of *homo faber*. This scholarly creation had its repercussions in encouraging the overestimation of the singularity or uniqueness of Western culture in comparison with others (although all cultures are unique and incommensurate). The elaborate, embarrassing exercise in culture-narcissism soon became routine since it was not to be challenged for nearly a century. (It is important to point out that the *homo faber* idea is quite recent to humankind: it is

consistently absent in not just other cultures, but even within a large part of the West itself).

For instance, it was taken for granted that the system of production that got generated in the last century and a half in the West was the only one with any significance simply because in the light of the present – and to all appearances – it had apparently emerged as the dominant one. Therefore, its past was the only one worth considering. This notion was in turn bolstered by another: a self-generating model of technological development in which the historian attempted to trace the evolution of modern science and technology by working backward to the experiences and ways of thinking characteristic of Mediterranean antiquity. Thus the roots of modern technology were shown to be exclusively founded on the work of Greek and Roman thinkers, mathematicians, engineers, and observers of nature with no input from any other culture areas or people.

This brings us to the second aspect we have alluded to above, and this concerns the relationship between knowledge and power and the impact of this on interpretations of technology and culture. Throughout history, knowledge has generally remained closely linked with interests. Even when encyclopaedias, for instance, have traditionally sold themselves on the Francis Bacon principle that “knowledge is power,” they too have continued to reflect an undeclared, equally influential, political principle – that “power is knowledge.”

The intrusion of Europeans into non-European societies and the gradual establishing of political dominance and inequality between societies stimulated the inauguration of a new discourse about such societies. Political dominance came to be as routinely and unabashedly expressed in the form of knowledge as it was through the barrel of guns. Edward Said has already written on the invention of the discourse on “Orientalism” and its direct political uses. But there are less controversial discourses that have had even larger repercussions only now being acknowledged. As a result, much academic knowledge in the Western world about the non-Western world, particularly the latter's technology traditions, remains not only distorted or contaminated by the ethnic

concerns, goals, theories, obsessions, and peculiar assumptions of Western scholars and universities; it is still largely defined, legitimized, and decided by them irrespective of whether there is any concurrence from the non-Western world.

The combination of these two aspects proved deadly: the emerging conception of Western man alone as *homo faber*, once it took firm roots within the situation of political dominance, rendered any appreciation of technique elsewhere – technique not necessarily reflected only in tools or machines – difficult and often impossible. In fact, the combination helped inaugurate its very own dark age. For it generated among Western (and not a few non-Western) scholars several major assumptions concerning technology and culture. We shall discuss three of these.

The first emerged in relation to Western man's attitude toward the past, particularly with regard to preindustrial technology. *Homo faber* exercised his new found power over the past by deriding it: this is reflected in the rewriting of history from today's perspective in which the past is seen as mere prelude to the present. Earlier technological innovations are considered primitive precursors of later developments. Here we have a good example of the parochialism of the modern/Western mind as it proceeds to take experiences of technology and culture exclusive not just to the late twentieth and early twenty-first centuries but to extremely small segments of the world population and makes these the basis for investigating, analyzing, assessing, and judging the general activities of human societies over hundreds of years. This was the case even when such societies were not so technologically enamored, dependent, or controlled as some of them seem to be now.

The second assumption relates to humankind's so-called unique propensities for technology when compared with that of the animal world, an uncritical theory best summed up in a single word: speciesism. After deciding on the issue of the comparative technological competence of all living species in its own favor, the West came to the conclusion that the rest of

creation, because inferior, was expendable if so required to further its own scheme of things.

But it is the third assumption that concerns us most seriously here: it is the idea that Western man can be equally distinguished from non-Western societies as well on the ground that the latter, like the animal and other "lower" species, also lacked technological development as it emerged in the West.

This idea was appropriately reflected in academia in the emergence of two new sciences: the discipline of sociology, which focused on so-called advanced societies and their flair for technology; and the subject of anthropology which occupied itself with non-Western cultures, limited to primitive or preindustrial tools. Anthropology's political origins have been blandly asserted by Claude Levi-Strauss in his controversial Smithsonian lecture:

Anthropology is not a dispassionate science like astronomy, which springs from the contemplation of things at a distance. It is the outcome of a historical process which has made the larger part of mankind subservient to the other, and during which millions of innocent human beings have had their resources plundered and their institutions and beliefs destroyed, whilst they themselves were ruthlessly killed, thrown into bondage, and contaminated by diseases they were unable to resist. Anthropology is daughter to this era of violence: its capacity to assess more objectively the facts pertaining to the human condition reflects, on the epistemological level, a state of affairs in which one part of mankind treated the other as an object.

It is within such an imperialist context that the histories and technological experience of non-Western societies could be written off or ignored: the latter, after all, were conquered peoples. When technology is seen through an anthropological prism, the emerging picture is bound to be far removed in character from a scenario that emerges from a sociological perspective. What is more, it is bound to be even more far removed from reality itself.

Some impression of that reality is discernible in the period before political dominance began to corrupt the objectivity of knowledge. Before the so-called "voyages of discovery," though non-Europeans were conceived as fantastic, wild, opulent, even monstrous, they were rarely

considered inferior or backward; and even the actual European encounter with the scientific, technologic and medical traditions of non-Western societies was different from what eventually became the stuff of politically directed myths. In fact, from the day that the Portuguese mariner Vasco da Gama landed in India until almost three centuries later, Asia had a larger and more powerful impact on Europe than is normally recognized. Donald Lach has appropriately titled the first volume in his *Asia in the Making of Europe* "The Century of Wonder." It was not without reason that an Englishman of the time addressed the Indian Emperor by describing himself as "the smallest particle of sand, John Russel, President of the East India Company with his forehead at command rubbed on the ground." Nor can we forget that the first presents offered by da Gama to the King of Calicut included some striped cloth, hats, strings of coral beads, wash basins and jars of oil and honey. The king's officers naturally found them laughable.

It would take a few more decades before the Europeans landing in the Indian subcontinent would notice anything beyond gold and spices. But by 1720 and for a period of up to a 100 years, a new category of observers came visiting, some from newly formed learned societies in England. Their detailed reports were a result of the European quest for useful knowledge in different fields.

In his pioneering volume, *Indian Science and Technology in the Eighteenth Century*, the Indian historian Dharampal includes several accounts from these observers which describe among others the Indian techniques of inoculation against smallpox and plastic surgery. (While the first was eventually banned by the English, the latter was learnt, adopted, and developed). The accounts also document Indian processes like the making of ice, mortar, and waterproofing for the bottoms of ships; water mills, agricultural implements like the drill plough, water harvesting and irrigation works, and the manufacture of iron and of a special steel called *wootz*.

More techniques (like those involved, for instance, in the manufacture of Indian textiles) are described in *DeColonizing History* (Alvares,

1991) and *Science and Technology in Indian Culture* (Rahman, 1984). But even this documentation, impressive as it is, is now recognized to be but the tip of the proverbial iceberg.

The Chinese, like the Indians at Calicut, had a similar experience with an embassy and its gifts from London. The edict of Qian Long to the embassy is worth quoting: "There is nothing we lack, as your principal envoy and others have themselves observed. We have never set much store on strange or ingenious objects, nor do we need any of your country's manufactures" (Fairbank, 1971).

Immediately after the encounter, the graph of European reaction rises with esteem and wonder; and then, as political conquest and overlordship increase, the graph alters course and begins to record increasing denigration. A remarkable transformation of image thus takes place as the political relationship between Europe and non-European societies changes to the advantage of the former, rendering the Europeanization of the world picture almost an act of divine will.

By 1850, political dominance over the non-Western world was clearly installing distorted ideas not only about that part of the world but rebounding to distort Western man's image of himself as well. Already by 1835, for instance, the British had acquired a flattering notion of their own civilization (Victorian England was seen to be at the top of the pyramid of civilization) and a thorough-going contempt for Asia.

This contempt finds expression in the famous Minute of Lord Babington Macaulay:

I have never found one amongst them (the orientals) who could deny that a single shelf of a good European library was worth the whole native literature of India and Arabia. . . It is, I believe, no exaggeration to say that all the historical information which has been collected from all the books written in the Sanskrit language is less valuable than what may be found in the most paltry abridgment used at preparatory schools in England. In every branch of physical or moral philosophy the relative position of the two nations is nearly the same.

Dharampal has produced an interesting record of these assessments of science and technology in India among Western observers as the

relationship between India and Britain changed to Britain's advantage.

Regarding the question of Indian astronomy, he discusses the case of Prof. John Playfair, Professor of Mathematics at the University of Edinburgh and an academican of distinction. Playfair studied the accumulated European information then available on Indian astronomy and arrived at the conclusion that the Indian astronomical observations pertaining to the period 3,102 years BCE appeared to be correct in every text. This accuracy could only have been achieved either through complex astronomical calculations by the Indians or by direct observation in the year 3102 BCE. Playfair chose the latter. Opting for the former would have meant admitting that "there had arisen a Newton among Brahmins to discover that universal principle which connects, not only the most distant regions of space, but the most remote periods of duration, and a De La Grange, to trace, through the immensity of both its most subtle and complicated operations."

Similar attitudes prevailed concerning the knowledge of how Indians produced *wootz*. Heath, founder of the Indian Iron and Steel Company and later prominently connected with the development of the steel industry in Sheffield, wrote "... iron is converted into case steel by the natives of India, in two hours and a half, with an application of heat that in this country, would be considered quite inadequate to produce such an effect; while at Sheffield it requires at least four hours to melt blistered steel in wind-furnaces of the best construction, although the crucibles in which the steel is melted, are at a white heat when the metal is put into them, and in the Indian process, the crucibles are put into the furnace quite cold."

However, Heath would not admit that the Indian practice was based on knowledge "of the theory of operations," simply because "the theory of it can only be explained by the lights of modern chemistry."

By the beginning of this century, the Western mind had already convinced itself that Western science and philosophy were the only approach to metaphysical truth ever attained by the human

species and that the Christian religion provided wisdom and insight incumbent on all people everywhere to believe.

The result is reflected in the output of academia: a "history of art" turned out to be nothing but a history of European art and a "history of ethics" a history of Western ethics. While European music was music, everything else remained mere anthropology. The contemporary evaluation of human activity in the West as compared with the non-Western world was unabashedly provided by the late Jacob Bronowski in the *Ascent of Man* in words almost echoing Macaulay in 1837:

We have to understand that the world can only be grasped by action, not by contemplation. The hand is more important than the eye. We are not one of those resigned, contemplative civilizations of the Far East or the Middle Ages, that believed that the world has only to be seen and thought about and who practiced no science in the form that is characteristic for us. We are active; and indeed we know, as something more than a symbolic accident in the evolution of man, that it is the hand that drives the subsequent evolution of the brain. We find tools today made by man before he became man. Benjamin Franklin in 1778 called man a 'tool-making animal' and that is right.

Now, there were obviously perverse consequences of such a view: scholars in several non-Western societies, schooled in an educational system imposed on their societies through the colonial establishment, readily incorporated similar ideas about their own histories. In an article in *Nature* 35 years ago, Joseph Needham had to chide a native scholar of Thailand for claiming that his own people had not made any contribution to science despite compelling evidence to the contrary. Nevertheless, the colonization project succeeded in convincing many non-European intellectuals and scholars that only the West was active. They facilely accepted the idea that activity per se was desirable compared to judicious or necessary activity; that only the West was capable of thinking in the abstract sense. If this opinion were carried to its logical conclusion, it would appear that if the rest of humankind had survived for hundreds of years, this must be due to some form of manna falling providentially from the heavens.

The damage done by these years of extremely ideological scholarship and a ruinous ethnocentrism to the history of technology was bad enough. Predictably, the impression of an empty technological wilderness invented by Western scholarship about non-Western societies had a parallel, simultaneous, destructive impact on the assessment of their cultures as well. So insidious was the nature of this outrageous assumption regarding Western and non-Western abilities, that even Joseph Needham, Mark Elwin, Abdur Rahman and a host of other scholars participated in pointless debates which often took it for granted. One major debate, for example, focused on why China (and India) did not produce either modern science or an industrial revolution on the European pattern, especially since Chinese technology had already reached a level of sophistication not yet attained in any other part of the world as late as the fifteenth century.

Attempted answers compared and contrasted the internal conditions within Chinese society with those within Europe; the argument eventually succeeded in establishing the conclusion that no scientific or industrial revolution occurred in China because the social conditions in China were not the same as those within Europe. Thereafter, a host of cultural and social factors were dragged out of context and labeled probable "obstacles" either to the development of technology or modern science.

A critique of the three assumptions we have surveyed above therefore becomes compelling and inevitable, if we are to eschew their myriad fallacies in future. We shall take each in turn.

The idea that the past was merely a prelude, and a primitive one at that, may come naturally to anyone who has begun to feel that the present era of technical change is inevitable. Yet future societies may assess their past (our today) basing themselves on values other than those celebrating mere technical change. Already mindless technical change and built-in technological obsolescence have been assaulted by several global thinkers on the ground of ecological unsustainability and resource scarcity. It would also be wrong to think that because man did not have technology as he now does, he was

necessarily impoverished. If there is anything the past gives us it is this positive impression of survival in all kinds of environmental scenarios. There is also evidence of more widely dispersed creativity when man was not submerged by technology than there is today. In many areas of human experience, we are yet to match even the technological achievements of the past which were driven by values other than mere complexity for its own sake or profit.

A similar argument may be used against the assumption that humankind is the only tool-making species there is. Several naturalists and ethologists have documented the diversity of nature's schemes at fabrication; most notably, Felix Paturi in his *Nature, Mother of Invention* and Karl von Frisch in *Animal Architecture*. Scholars like Lewis Mumford have gone further in stating quite bluntly that in their expression of certain technical abilities other species have for long been more knowledgeable than man.

Insects, birds and animals, for example, have made far more radical innovations in the fabrication of containers, with their intricate nests and bowers, their geometric beehives, their urbanoid anthills, and termitaries, their beaver lodges, than man's ancestors had achieved in the making of tools until the emergence of homo sapiens. In short, if technical proficiency alone were sufficient to identify and foster intelligence, man was for long a dullard, compared with many other species.

Niko Tinbergen, another ethologist, after years of close observation of other species, has come to the following conclusion: "It was said that (1) animals cannot learn; (2) animals cannot conceptualize; (3) cannot plan ahead; (4) cannot use, much less make tools; (5) it was said they have no language; (6) they cannot count; (7) they lack artistic sense; and (8) they lack all ethical sense." All of these statements, says Tinbergen, are untrue.

It cannot be said therefore that, in contrast with other species, humankind alone is a tool-maker. Thus the attempt to distinguish man from other living species because of his tool-making capacity is now seen to be a result of limited knowledge and unwarranted assumption

of qualitative discontinuities between human beings and other species. It will also be useful to recall here that the ability to fabricate and organize is not a singular human trait – it is an intrinsic feature of nature since nature can exist only in a given form, whether at its most primary constituents at the subatomic level or even at the level of crystalline structures or the multiple tiers of a primary forest.

However, it is the third assumption – concerning the West's genius for technology and the rest of the world's incompetence in the same department – that contains the greatest mythological component of them all.

As we shall presently see, such an assumption has not only no historical basis, it is in fact contrary to historical and even to contemporary evidence. As for the gift of Greek rationality, suffice it to say that for 2,000 years it gave no technological advantage to those who had it over those who did not. On the contrary, major scientific concepts, technological artifacts, tools, and instruments emerged in cultures that had nothing to do with either Greece or Rome.

The other problem with this assumption is it cannot even cope with the long established view that the science and technology traditions of most societies, particularly so of the West, are in significant ways mixed traditions. Even the little that we know about it indicates that the cross-cultural borrowing of technics and technology is impressive. Thus a very large number of critical inventions from both India and China helped fill significant gaps in the technological development of the West. A simple example from Francis Bacon's work will suffice to illustrate this point. He wrote:

It is well to observe the force and virtue and consequences of discoveries. These are to be seen nowhere more conspicuously than in those three which were unknown to the ancients, and of which the origin, though recent, is obscure and inglorious; namely, printing, ► [gunpowder](#), and the magnet. For these three have changed the whole face and state of things throughout the world, the first in literature, the second in warfare, and the third in navigation; whence have followed innumerable changes; inasmuch that no empire, no sect, no star, seems to have exerted greater power and influence in human affairs than these mechanical discoveries.

Now all these three mechanical discoveries were Chinese. Yet here again Western scholars have found it hard to acknowledge their origin. Borrowing of techniques from India is easily documented as well.

The documentation of technology in other cultures is only beginning. For example, it was only in 1974 that Sang Woon Jeon's *Science and Technology in Korea* appeared. There is as yet no major record of technology in Africa or South America though there is now available a large volume of documented evidence that both areas were rich in tools and techniques, from metallurgy to textiles.

In India, the other large storehouse of useful and appropriate tools (some still in productive use), the most extensive documentation of technology has only recently commenced, sparked in part by Dharampal's *Indian Science and Technology in the Eighteenth Century* and the work of scholars like Abdur Rahman.

The immediate impact of these reinvigorated investigations, stimulated largely by political independence, is a fresh debate over the issue of technology and culture: the old assumption of one technology and one culture in which others are seen to make a few, presumably inconsequential, contributions, is in tatters. Whatever its own pretensions to be the only viable culture, the West is finally being seen by non-Western societies as only one among several: a certain balance between cultures gets restored even though economic inequality persists. In fact, in some cases the pendulum has swung to the other side with cultures unabashedly resuming their traditions. There has naturally been a reverberation in the climate of ideas.

Changes in perception of this kind have already come about in other academic disciplines. To cite just one example, world histories were once written as if Europe were the center of the planet, if not the cosmos. There has been progress since: Geoffrey Barraclough and Leon Stavrianos, for instance, have both succeeded in producing comprehensive histories which avoid the older Eurocentric perspectives.

But even assuming we are able to produce, culture by culture, a fairly objective and

comprehensive record of science, technology, and medicine, we would still be uncomfortably close to the pet obsession and perception of the present epoch. If there is anything the recent past has shown us, it is that we can be all too zealous judges in our own cause. We continue to celebrate uncritically our technological feats even when we know that the principal criterion of success for any species (and the human species is no exception) is primarily its ability to survive.

Therefore, it may be best not to get trapped in the debates on what is basically a subhistory: the history of slave-machines or automation or the recent machine-propensity of some cultures. After all, the *homo faber* concept is itself a distorted reflection of the natural endowments of the human species, an example of reductionist thinking. We know now that reductionism readily distorts knowledge, often pauperizes it, but rarely enhances it.

What is required in the circumstances then is a paradigm shift. I would like to suggest this can be achieved by replacing the heavily loaded term "technology" (too close identified with externalized objects) with the more neutral word, "technique." Technique has a larger ambit than technology and does not necessarily express itself only in the form of tools or artifacts. For the moment, we may define it briefly as every culture's distinct means of achieving its purposes. The natural propensity of human beings is to rely on technique, not technology, for while it has been proven that we can survive without technology, we cannot survive without technique.

Thus there can be no technique without culture, no culture without technique. An investigation into a culture's techniques is bound to be considerably more difficult than the recording of a culture's artifacts. The important gain here would be that we would begin with a more democratic assumption: that there is no culture without a system of techniques. Such a postulate would inoculate us effectively against methodological, ethnocentric, and other fatal flaws the *homo faber* concept was both parent and heir to. It would nip in the bud any undesirable future forays into cultural narcissism or ethnocentric discourse.

If this is indeed so, the more logical assumption would be that every culture has relied on a corresponding system of techniques that has guaranteed survival. Understood in this way, it makes far better sense to talk of Western technique (even though today largely expressed in the form of technology), or African, Indian, Chinese, Maya, or Arabic techniques of survival (in which technology may not be given that importance for fairly valid reasons). But even a relatively low importance given to technology could never mean a poverty of technique. The idea that the human species is technique-natured could be empirically falsified if a human society could be found that lacked technique – and not just machines or artifacts.

Technique, then, is nothing but the permanent but dynamic expression of an individual culture. Cultures can only express themselves or survive through technique: the alternative is chaos. Nonhuman species may be guided in the exercise of technique by inflexible inborn patterns of behavior. But the human world is as rigorously bound by the controls imposed by the symbolic universe that emerged as a substitute for weakened instinctual patterns. Myth, for instance, is technique. Interaction with (or manipulation of) nature may take place either through myth-making, scientific construction, and myriad other ways. All are expressions of the symbolic universe human beings inherit because they are human beings.

Thus we share the necessity of functioning through technique – not just through tools – with other living species – from the mammoth geobiological processes of Gaia to the cross-pollination of the rice plant to species of bird and animals, some of which, like the bower bird, are more prone to technology than others. Thus the so-called potter-wasp is known for its technique in constructing what we human beings culturally recognize as pots: however, the small vessels are the conclusion of technique: without it, there would be no "pot," no propagation and, therefore, no survival.

This will also explain why so-called primitive societies are often more complex in their socio-cultural arrangements – their rich fund of

botanical knowledge, slash-and-burn techniques, elaborate myths are as much an expression of technique – than modern societies.

Our new paradigm – based on a thoroughgoing analysis of technique – will enable us to concentrate more effectively on those aspects of human experience in non-Western societies where there may be appropriate development of technology (as in India and China) but a superabundance yet of technique. A large number of these, particularly in India or in the Islamic cultures, may be located squarely within the domain of the sacred. They would be unintelligible outside such a framework of understanding.

We shall also observe in such societies that even where there is sophisticated technology, it retains an unobtrusive (not invasive) character. This can be seen from the merged outlines of Arab architecture to the irrigation works of South India or Sri Lanka.

An encyclopaedia of non-Western science, technology, and medicine may restrict its scheme to a bare description of the evolution of machines or artifacts incompetently covered by earlier conventional Western works, but it must do so guided by the background of the larger canvas of technique. Here the scholar will eventually examine theories of language in the same detailed manner as he would the culture and preparation of food or the control of breath – all extremely detailed sciences in India and China; he would examine irrigation and animal husbandry techniques, the domestication of cultivars of crop plants, record the elaborate knowledge of plants and of the human body, and seek to understand theories of cosmic phenomena and of the behavior of annual events like the monsoons.

The aim of the historian is to describe the nature of this individual system and not place it within a hierarchical ordering of societies. His task is to document this immense richness, not endeavor to swamp and drive it into oblivion on the questionable assumption that Western technology is the only direction that human technique will take. The growing anxiety over Western technology is closely associated with the threat it is perceived to pose to the fate of the planet and to survival. We may have to examine its history

clinically to diagnose why it has generated the kind of problems it poses for humankind. Here, only a proper study of technique and culture within non-Western societies (and not as Forbes hoped, the event of Easter) will bring some balance and provide urgent clues to the origins of what Jamal-ud-din described as the illness of occidentosis, the plague of the West.

Technology and Environment

Arnold Pacey

The development of technology has usually been socially determined, changing in direction as different social formations have emerged. For example, there are important distinctions to be made between, first, small communities of farmers or dispersed groups of hunters with technologies outstanding chiefly for their adaptation to local *environments*; second, the larger kingdoms and empires, whose technology tended to be *engineering-centred*; and third, trading communities and merchants or entrepreneurs with *production-centred* technologies.

An initial problem in discussing technologies of the first kind is nomenclature. J. S. Weiner, who has discussed the remarkable protective clothing developed by the Inuit for life in the Arctic, has described these people as “the great pioneers of micro-climatological bioengineering”. This tribute to the control of body heat loss achieved by Inuit clothing is well deserved but places the skills of Arctic people within the wrong frame of reference. Their technology was environment-centred, not engineering-centred. On the one hand, they were adapting to a very demanding environment; on the other, they were making very efficient use of environmental resources. Thus, the animals hunted for meat were also a source of oil for lamps, bone for making needles and other tools, and the skins, intestines, and fibres from which clothing was made.

Archaeological evidence suggests that the invention of tailored skin clothing adequate to enable people to winter in the Arctic was accomplished in Siberia around 2000 BCE. After that, it was several centuries before oil lamps, houses built of snow, and dog sleds were developed by the people of the Dorset Culture, based on Baffin Island. Later still, improved boats and harpoons were developed by the Alaskan Inuit.

All these inventions, quite clearly, were the work of small, dispersed groups without centralized organization, and all were responses to an exacting environment. Perhaps what we ought also to remember is that for the Inuit, as for most non-Western peoples, the environment was endowed with personal and spiritual meanings and with magical qualities. It was not merely the object of detached, if concerned, analysis that it has become for most Westerners. Thus, their technology was based on an organic worldview.

The same points can be made about peoples inhabiting other environments, such as rainforests, deserts, steppes, or coastal and island situations. The efficiency with which resources were used by such people is illustrated by the estimate that in 1500 CE the Amazon basin supported a somewhat larger population than it did in 1990, yet without the extent of destruction of forest and fishery resources now taking place. Fruits, nuts, leaves, seeds, and roots were gathered for use as food and medicine. Fish and animals were caught, often using poison tipped spears, but with less ecological disturbance.

In some rainforests, notably in Central America as well as in Asia and Africa, people developed a form of agriculture in which a great variety of crops was raised while extensive tree cover was retained. Cereals such as corn in the Americas or rice in Southeast Asia were grown in forest glades with shade-tolerant vegetables under trees. Those trees that were left unfelled or were newly planted would be selected according to whether they produced fruit, nuts, timber, fodder, or *materia medica*. Thus, an artificial rainforest was formed in a system often referred to as forest farming, forest inter-culture, layered gardening or, more recently, agroforestry. The key point – whatever the name – is that there would always be tree cover, and usually other vegetation, to protect the soil from erosion and to retain plant nutrients. By contrast, where rainforest is cleared for conventional western style agriculture, soils become degraded very rapidly.

In Africa, rainforest crop production became widespread only after the banana and Asian yam

were introduced on the east coast by Indonesian traders and colonists around 400–500 CE. In quite a short space of time, these crops were adopted by many gardeners across the continent, enabling populations in forested areas to increase considerably. In Central America, archaeologists have now shown that the Maya culture used forest farming with high yielding nut trees and manioc (cassava) as major crops around 600–900 CE.

Other environment-centred technologies were those of people living in hot, dry, and semi-desert conditions who evolved sophisticated water conservation techniques. Some of these made use of small structures, such as check dams in gullies and spreader dikes on flatter ground – for example, in northern Mexico and Arizona – or else stone lines on contours (in the African Sahel). Others practiced the careful planning of fields in relation to rainwater catchment areas, and the construction of bunds (embankments or dikes) to channel water and hold it on the land. Among the most elaborate ► [rainwater harvesting](#) systems of this kind were those of Nabataean farmers in the Negev Desert in Israel from about 200 BCE, and comparable systems in Morocco and elsewhere in North Africa. Small dams, river diversions, and the Persian ► [qanat](#) (wells linked by a tunnel; Fig. 1) were other means of providing irrigation water to crops on a small scale.

Consideration of environment-centred techniques such as these offers a distinct perspective on early technology quite unlike the conventional view based on the materials from which tools were made, namely, stone, bronze, and iron. That view seeks to discover a pattern of tool use and metalworking skill common to all human societies, and ignores the environmental particularism emphasized here. It parallels the modern assumption that the principles of technology are independent of cultural values and underestimates the different ways in which human societies explored the varying surroundings in which they lived. By contrast, a perspective based on environmental adaptation allows one to recognize the extraordinary sophistication of some peoples who nominally remained in the “Stone Age” even in the early twentieth century, including the Inuit and some rainforest communities.

Viewed from another angle, however, the Neolithic period in the later Stone Age does seem to have been a time of particularly important innovation, at least for western Asia. It is associated with the first domestication of crops and livestock, and hence the invention of agriculture, probably associated with the earliest used of some of the water conservation techniques previously discussed. Complementing these innovations were others, such as pottery (and soon after, the potter’s wheel), grain milling, tool-making, and textiles (with the looms on which they were woven). Many of these innovations relate to the domestic sphere of life, and it is likely, therefore, that many of the inventors concerned were women.

It would be a mistake, however, to assume that the invention of agriculture, the domestication of plants, and the appearance of pottery or textiles were unique events, each occurring only once in human history, in one part of Asia and then diffusing to other regions. Independent inventions undoubtedly occurred, just as different crops were domesticated in various places and at different times. For example, about 1500 BCE, corn (i.e. maize) and pottery were both known in Mexico, but not in Peru, where beans and peppers were cultivated. Thus, the two cultures may have developed agriculture independently of one another. Moreover, some plants were still being newly domesticated in the twentieth century, for one reaction to deforestation in Africa has been to cultivate a number of fruits and vegetables that people had collected from the wild until the loss of forest cover threatened their existence. Reports from Kenya show how modern gardeners, usually women, have selected from wild varieties and have produced strains adapted for garden conditions.

Engineering-centred technologies developed in a very different context. They were characteristic mainly of kingdoms or empires whose labour resources and administration made large-scale construction works possible. One view of the origins of engineering is that once agriculture was established, irrigation became necessary in many of the warm, dry countries of western and southern Asia to produce sufficient food for

Technology and Environment,

Fig. 1 Two *qanat* tunnels in a typical landscape, where rainwater running off mountains replenishes groundwater beneath the sand and gravel of the lower slopes (water-bearing gravel is shown darker than the dry gravel layer above). The ground penetrated by one of the *qanats* is shown in cut-away section to demonstrate how the tunnel gives access to water trapped by impervious rock. The section also shows how the tunnel is lined with earthenware rings when passing through sand or gravel layers which might otherwise cave in. *Qanat* tunnels were excavated from the bottoms of a series of well shafts, with the “mother well” at the upstream end dug first to prove the existence of water. The tunnels were sometimes several kilometres long with their route evident on the surface from the line of well shafts, as on the right of the picture (Illustration by Hazel Cotterell based on sketches by Arnold Pacey; reproduced from Pacey, 1990, p. 86)

growing populations. The dams and canal systems necessary for irrigation could not have been constructed, it is argued, without recruiting a large labour force, and that in turn could not have been done except in centrally organized kingdoms. In this view, the need for irrigation canals and other hydraulic works dictated the formation of centralized government administrations with the coercive power and management skills needed to organize large-scale construction works.

This theory about how hydraulic civilizations evolved does not apply everywhere, however, since empirical evidence shows that in many

areas where irrigation was practiced, farmers did the essential earth moving and engineering work themselves, or with their neighbours through local systems of cooperation, but without central organization. This seems to be true for rice culture in China, according to Francesca Bray. Some of the biggest centrally organized engineering schemes prior to 605 CE, involving thousands of labourers, were not for irrigation but for construction of transport canals for carrying grain to the capital. However, flood control and irrigation in North China did depend on large-scale works, so the evidence is not clear-cut.

In Mesopotamia and Egypt, much early irrigation was also on a small scale, dependent on manually operated water-raising devices such as the *shaduf* (a device consisting of a long suspended pole weighted at one end and having a bucket at the other end). The type of crops grown and the seasons of cultivation meant that there were fewer water requirements in early agriculture than after the agricultural revolution of the Islamic period (after 700 CE), when crops that demanded more water (including rice) were more widely grown. In Mesopotamia, large-scale works were needed at an early date, but in most places it is hard to argue that the requirements of hydraulic management were sufficiently exacting to determine the development of centrally organized states. On the contrary, the prior existence of centralized political power made possible a wide range of construction programs that included fortifications, monuments, and temples, as well as hydraulic works, and it is impossible to say which kind of engineering came first. One of the earliest sites to provide evidence is Jericho, where defensive walls, but also big water tanks, have been found dating from before 6000 BCE. The pyramids of Egypt were among the largest construction projects ever conceived when they were begun about 2600 BCE. But a comparable amount of labour may have gone into embankments and canals built at about the same time for flood control and irrigation by the Sumerians in Mesopotamia. Thus, the evidence does not give a clear picture of hydraulic requirements, rather than other construction works, forcing the pace in either administration or engineering.

That brings us to a second hypothesis about how engineering-centred technologies evolved, suggested by Lewis Mumford and some like-minded commentators. This is the view that such technologies were related to the invention of warfare, for indeed, organized lethal warfare had to be invented, and this may have happened during the Neolithic age, possibly following the invention of agriculture. The reasoning here is that agriculture made possible denser populations within which social tensions were inevitable and from which large bodies of fighters could be recruited, while at the same time, agriculture

produced the economic surplus needed to pay for arms and fortifications. It is suggested, also, that centralized governments and military institutions began to evolve about this time, and provided a model of how large bodies of people could be organized and supervised, not only in combat, but also in constructing fortifications – or dams, canals, and pyramids.

Needless to say, the development of warfare provided other stimuli to engineering-centred technology. Mechanized fighting may be said to have begun with the clumsy, four-wheeled Sumerian chariot of about 2400 BCE. The Hittites, whose empire overlapped Asia Minor and Syria, invented some of the first effective siege engines soon after. Horses were initially used mainly for drawing chariots, their full potential for warfare only emerging much later with the invention of the stirrup and its associated harness. This freed the rider's arms to use weapons while he remained securely in the saddle.

Engineering-centred technologies in ancient civilizations can appear to be focused very largely on large-scale hydraulic works and on military engineering. In addition, one bias in the western understanding of technology is a tendency to focus on the wheel, and on machines using wheels, such as the early chariots just mentioned. But wheels did not always mean progress. Wheeled vehicles were used in the North and West of Africa around 500 BCE, regularly crossing the Sahara Desert. Yet they went out of use later when the camel was introduced, because camels provided much more efficient means of transport in a region with sandy deserts and no paved roads. For parallel reasons, wheeled vehicles were not much used in southern Asia. In Central America, rollers and wheeled toys have been found, but in a region where there were no animals capable of pulling carts, little could be gained by developing such devices.

The potter's wheels (and later, lathes working on similar principles) were probably the first machines to use the wheel, around 3000 BCE. Much later, a basic water-powered corn mill evolved, with a vertical axle and propeller-like blades below the millstones. One view is that this was a Greek invention made about the time of

Alexander the Great. Another view, however, is that it arose out of the Hittite tradition of engineering which had earlier pioneered so much military equipment. After the Hittite empire collapsed around 1200 BCE, some aspects of its culture survived in Syria, and itinerant craftsmen perhaps reached Mesopotamia and Iran. It was probably in one of these countries that vertical-axle water mills originated. Since the same type of mill appeared in China not long afterwards, one might reasonably look for its origins close to trade routes with China. A related invention of the same period was the water-raising wheel or *noria*, a basic water wheel with a horizontal axle and pots or buckets attached to its rim in which water could be raised (Fig. 2).

Some thousand years later, Iran was certainly where an early type of windmill was invented. It worked in much the same way as the vertical-axle water mill, though mounted in a tower with vents in the walls to catch the wind (Fig. 3).

In both Iran and Iraq extensive use was made of water wheels of several types, and some large dams were erected. Other uses of water power in this region around the year 1000 CE were in sugar cane crushing mills, fulling mills, and mills for preparing the pulp for paper-making. Paper manufacturing had been introduced at Baghdad in 794 CE, probably with the help of Chinese workmen, and water wheels were used to work hammers that made pulp from 950 CE.

Technology and Environment,

Fig. 2 Water-raising wheel of the type known as the *noria*. This is an undershot water wheel, driven by the flow of water in the stream running underneath it. The jars tied to the rim fill from the stream and then empty into the trough at the high level (Illustration by Hazel Cotterell; reproduced from Pacey, 1990, p. 11)

Technology and Environment,

Fig. 3 Persian-type windmill showing how shield walls were designed to funnel wind onto the sails, which rotated on a vertical shaft. The way the mill worked is most clearly seen from the plan (*lower illustration*). The perspective view shows how the shield walls of later mills formed a towering open structure built of sun-dried bricks with a small room containing the millstones underneath. The earliest mills seem to have been of different design with the millstones supported by the shield walls at the top of the structure (Illustration by Arnold Pacey, based on photographs by Dick Day of a windmill in Afghanistan; reproduced from Pacey, 1990, p. 12)

Production-centred technologies can be said to include devices such as corn mills, or iron smelting, or the porcelain industry which developed in China. Other evidence of production technologies in China includes several inventions that first appeared there in the three or four centuries prior to 1250. They include spinning wheels, silk-winding machines, and water-powered mills for spinning and winding thread.

Much production of pottery and textiles would be carried on in a domestic context, but there were also instances of large-scale production, of which the most characteristic unit in South Asia was the *karkhana* of Mughal India, or the specialist porcelain factory in China. At one time 4,000 silk workers were employed in karkhanas in Delhi, some of them conscripted.

Production for purposes of trade had to be more flexibly organized and flourished most

markedly where merchants could function independently. By 1700, India had become the world's greatest exporter of textiles, sending its cotton cloth to Europe, Africa, and many destinations in Asia. Both Indian and foreign merchants were involved, sometimes financed by the many Parsi and Gujarati bankers to be found in ports such as Surat.

It should not be thought, however, that proto-capitalist industrial organization was always favourable to the use of machines, water-powered or otherwise. The high quality of Indian textiles was achieved by painstaking handwork, as in the printing of designs on cloth (Fig. 4), and sometimes by a very fine division of labour. British observers noted that cotton cloth would sometimes be worked on by four people for every one employed on the same tasks in Europe. Thus the remarkably fine muslin produced in Bengal was

Technology and Environment,

Fig. 4 Indian technique for printing designs on cloth using a wooden block, applied by hand to transfer a mordant (rather than the dye itself) to the cloth. Mordants are chemical substances that made the cloth receptive to dye. First the wooden block carved with the flower pattern being printed is carefully placed in position (*top*), and then it is struck sharply with the right hand to transfer the mordant solution from the block to the cloth (Illustration by Hazel Cotterell based on sketches by Arnold Pacey; reproduced from Pacey, 1990, p. 85)

the result of many detailed processes which would be simplified and reduced to a single operation in the West.

Indian cloth was also noted for the fastness and brilliance of the colours with which it was dyed, mostly using vegetable dyes such as indigo and madder. However, some inorganic substances were also needed as mordants, to help dyes bond with textile fibres and often modifying the colour, and this gave rise to a significant chemical industry. For example, the alum used in madder dyeing was produced in Rajasthan by processing broken shale tipped as waste around copper mines (Fig. 5). These chemical processes were operated on a substantial scale but using labour-intensive methods and minimal equipment. Merchants and banks had ample funds to invest in the textile trade, but because wages were

low, there was little advantage in financing more productive equipment.

Technology is too often equated with engineering and hence with structures, machines, or equipment. However, a deeper understanding of technology in non-Western cultures demands awareness of subtleties in responses to the environment by which human survival was guaranteed in very varied conditions, and subtleties in the use of materials (such as dyes and mordants) by which high-quality production was achieved without machinery.

Thus while engineering-centred technologies that are easy to illustrate with pictures of machines are central to most people's image of what technology is about, a more fundamental view of technology must take account of responses to the environment that cannot easily

Technology and Environment,

Fig. 5 Alum production in Rajasthan, India, about the year 1800 CE. Shale tips associated with copper mines provided the raw material and can be seen in the background on the right. Shale was steeped in water in rows of pots on the tips. The liquid was then brought to the boiling house seen to the left where some water was evaporated off and the pots left to stand. Blue crystals of copper sulphate formed and were removed. After decanting the liquid and boiling it again, saltpetre was added. The alum was formed by reaction of the saltpetre with aluminium salts in the solution, and crystallized at the bottom of the pots (Illustration by Hazel Cotterell based on sketches by Arnold Pacey; reproduced from Pacey, 1990, p. 122)

be illustrated, such as ► [rainwater harvesting](#) or agroforestry where there are no machines to illustrate.

Technology in the Islamic World

Donald R. Hill

Hydraulic engineering was the most important technology of medieval Islam. Irrigation schemes supported a thriving agriculture and such schemes involved the construction of canals and *qanats* (see below), dams and water-raising machines. At the other end of the chain, water power was needed to process the raw agricultural products. In this article, we will begin with a survey of hydraulic engineering which will give us an overview of many of the significant aspects of Islamic technology.

Following this, a brief summary of a few other technologies will help us to appreciate the richness and diversity of Islamic material culture. The brevity of this summary is because of limited space and should not mislead readers into thinking that these technologies were insignificant, either in the social life of Islam or in the history of technology.

In Egypt, basin irrigation was in general use. This consists of leveling large plots of land adjacent to a river or canal, and surrounding each plot by dikes. When the river reaches a certain level the dikes are breached, allowing the water to inundate the plots. It remains there until the fertile sediment has settled, whereupon the surplus is drained back into the watercourse.

The regime of the Nile, with the predictable arrival of the flood, made Egypt particularly suitable for basin irrigation. Elsewhere in the Islamic world, however, perennial irrigation was, and is, practiced extensively on all the major river systems. As the name implies, it consists of watering crops regularly throughout the growing season by leading the water into small channels which form a matrix over the field. Water from a main artery – a river or a major canal – is diverted into supply canals, then into smaller irrigation canals, and so on to the fields. In many cases the systems operate entirely by gravity flow, but water-raising machines were used to overcome obstacles such as high banks, whether they were

natural or artificial. Perennial irrigation from wells, again using water-raising machines, is also extensively practiced in the Islamic world.

After the advent of Islam a number of existing systems were extended in order to cater for the needs of newly founded cities. Completely new systems were also constructed. In central Iraq the Muslims inherited the network constructed by their predecessors, the Sasānid dynasty of Persia. The major expansion occurred after the foundation of Baghdad in AD 762. The great Nahrawān canal, which left the east bank of the Tigris a short distance below Takrīt, was extended southward.

The rivers ʿUzaym and Diyāla, which discharge into the Nahrawān from the east, were dammed by the Muslim engineers to provide water for a huge irrigated area. Further south, to the west of the Shaṭṭ al-ʿArab, the city of Basra was founded in the seventh century. Originally it was simply an army encampment consisting of reed huts, but soon it grew into a great city which had no rival in Islam before the foundation of Baghdad. Gradually, in the last decades of the seventh and the first decades of the eighth centuries a vast network of canals was constructed to serve the demands of a thriving agriculture.

Other important systems were based upon the rivers in the province of Khurāsān, then much larger than the eastern Iranian province of the same name. Some of the most impressive networks were based upon the river Murghāb, upon which stands the city of Marv. In the tenth century the system was controlled by a specially appointed Amir who had 10,000 men under him, each with an appointed task. This Amir is said to have had more authority than the prefect of Marv. Other important schemes in the east were those centered on the cities of Bukhārā and Samarqand and on the lower reaches of the Amu Darya (Oxus) river.

In Spain, the Muslims greatly extended the irrigation schemes that had been constructed by the Romans and Visigoths. Syrian irrigation technology – large contingents of the conquering armies were from Syria – was applied in Spain, where the climatic and hydraulic conditions of the rivers of the north were very similar to those

in Syria. The irrigation systems, such as those along the Guadalquivir river and those in the province of Valencia, were the basis of the agricultural prosperity of Muslim Spain. Indeed, systems such as that in Valencia, basically unchanged since Islamic times, continue to serve the needs of the province to the present day.

A particular technique, originating in Armenia about the eighth century BCE, and still in widespread use in modern Iran, was the ► [qanat](#), an almost horizontal underground conduit that conducts water from an aquifer to the place where it is needed. For the preparatory work an experienced surveyor carefully examines the alluvial fans, the terrestrial equivalent of a river delta formation, in the general location of the proposed *qanat*, looking for traces of seepage on the surface and often for a barely noticeable change in vegetation, before deciding where the trial well is to be dug. When a successful trial well has been excavated, it is now known as the mother well. The surveyor levels from this point to the outlet of the *qanat*, marking the positions and levels of the proposed ventilation shafts at 30–50 m intervals. These shafts also provide for excavation of the spoil. A skilled artisan (*muqanni*) then begins work with his assistants by driving the conduit into the alluvial fan, starting at the mouth. At first the conduit is an open channel, but it soon becomes a tunnel. Another team sinks ventilation shafts ahead of the tunnelers, and laborers haul up the spoil to the surface through these shafts by means of a windlass. The tunnel is about 1 m wide by 1.5 m high; in soft soil hoops of baked clay, oval in shape, have to be used as reinforcement. As the work nears the mother well, great care has to be taken in case a *muqanni* misjudges the distance and strikes the full well, in which case he might be swept away by the sudden flow.

The construction of canals, *qanats*, and other public works required the assistance of skilled surveyors. The earlier methods of leveling were rather slow and tedious. This involved stretching a string between two staffs divided into graduations and held vertically. A level was suspended to the center of the string. One type, for example, was an inverted isosceles triangular frame suspended by hooks to the string. Fixed to the

center of the horizontal leg was a plumb line. One end of the string was moved up or down the staff until the plumb line passed through the inverted apex of the triangle, at which point the string was level. The difference in level between the two staffs was noted. In the eleventh century a level was introduced akin to our modern instrument but without, of course, any telescopic or electronic aids. A thin copper tube rotating on a circular plate that was suspended to a “gallows” was aimed horizontally on to a level staff. The reading gave the difference in level between the two points. The rises and falls along the route of the survey, summed algebraically, gave the level difference required. Triangulation, by which the heights and distances of objects, whether accessible or not, could be determined was usually carried out by the astrolabe. Quantity surveying methods were very similar to those in use today. The amount of excavation for a canal, for instance, was first calculated. Then, by applying known unit rates, the engineer worked out the number of excavators, laborers, foremen, and supervisors. From these results he prepared a Bill of Quantities which was used for measuring progress and paying the contractor.

The main purpose of dams was to divert water from rivers into irrigation systems. Our knowledge of Muslim dams comes from two sources: reports in the works of Muslim geographers, and the examination of Muslim dams which have survived to the present day. In the east, one of the most impressive dams, known as the Band-i-Amir, was built in 960 over the river Kūr in Iran, between Shirāz and Persepolis. As described by the tenth-century geographer ► [al-Muqaddasī](#), it was used to irrigate 300 villages. At each side of the dam, downstream, were ten water-raising wheels and ten water mills, all given extra power by the head of water impounded behind the dam. The dam was constructed throughout of masonry blocks, and the joints were made of cement mortar strengthened with lead dowels. The dam still exists and it is not surprising, given the solidity of its construction, that it has had such a long and useful life.

Also in Iran, at Kebar, about 15 miles south of Qum, is a dam which is very important in the history of dam construction. Built in the thirteenth century, it is the first known example of the true arch dam. It did not depend for its resistance to water pressure on gravity but was built as an arch, its convexity pointing upstream, and its sides were anchored securely into the rocky sides of the gorge in which it was built. The forces were transferred to the abutments, and it was considerably more slender than a gravity dam across a similar river.

A number of important Muslim dams were built in the Iberian peninsula. These included the dam at Cordoba with an overall length of 1,400 ft. Downstream from the dam were three millhouses that each contained four mills, as the geographer ► [al-Idrīsī](#) reported when he saw them in the twelfth century. Also below the dam is a large waterwheel. There are a series of eight dams on the river Turia in the province of Valencia. They are very securely built in order to withstand the sudden dangerous floods to which the river is subjected. They are also provided with desilting sluices, without which the canal intakes would soon become hopelessly choked.

These dams and their associated canals continue to provide for the needs of the province at the present time. It has been shown in modern measurements that the eight dams and their associated canals have a total capacity slightly less than that of the river. This, of course, raises the question whether or not the Muslims were able to gauge a river and then design their dams and canals to match. There seems no reason to doubt that they indeed had that capability.

Given that dam building had been an established practice since the times of the Sumerians and ancient Egyptians, it is not easy to isolate those elements that were Muslim innovations. On present evidence, it seems certain that the introduction of desilting sluices, the arch dam and hydropower were all Muslim inventions. The Muslims also probably perfected the technique of gauging rivers.

All the main water-raising machines were in existence in the Middle East before the advent of Islam. These included the Archimedean screw,

the well windlass, the *shādūf*, the *sāqiya* and the *norīa*. Because of their survival right up to the present day, and/or their importance in the development of machine technology, the last three of these are the most significant. The *shādūf* is illustrated as early as 2500 BCE in Akkadian reliefs, and it has remained in use throughout the world until now. Its success is due to its simplicity and its efficiency. It can be easily constructed by the village carpenter using local materials, and for low lifts it delivers substantial quantities of water. It consists of a long wooden pole suspended at a fulcrum to a wooden beam supported on columns. At the end of the short arm of the lever is a counterweight made of stone or clay. The bucket is suspended to the other end by a rope. The operator lowers the bucket and allows it to fill. It is then raised by the action of the counterweight and its contents are discharged into an irrigation ditch or a head tank.

The *sāqiya* was invented in Hellenistic Egypt, probably in the third century BCE. It is operated by an animal, usually a donkey, walking in a circle. On its shoulders and neck the animal wears a collar harness that transmits the power through two traces to a double-tree fastened to a drawbar. The drawbar passes through a hole in an upright shaft. This shaft carries the lantern-pinion, which is a type of gear-wheel consisting of two wooden discs separated by pins, the spaces between the pins being entered by the cogs of a vertical gear. This vertical gear has the cogs on one side of its disc and these protrude from the other side to form the wheel that carries the chain-of-pots, or potgarland. The component is therefore known as the potgarland wheel. It is erected on a horizontal axle over a well or other water source. The pots fill with water at the bottom of their travel and discharge at the top, like the shadoof, into a head tank or irrigation ditch. The *saqiya* was transited by the Muslims from the Middle East to Spain and eventually to the New World. In some areas it has retained its popularity to the present day.

The *norīa* is perhaps the most significant, from a technical viewpoint, of the traditional water-raising machines. Being driven by water, it is self-acting and requires the presence of neither

man nor animal for its operation. Essentially it is a large wheel constructed of timber. At intervals, paddles project outside the rim of the wheel, which is divided into compartments. The noria is provided with an iron axle and this is housed in bearings that are installed on columns over a running stream. As the wheel is rotated by the impact of the water on its paddles, the compartments fill with water at the bottom of their travel and discharge their contents at the top, usually into an aqueduct.

The point of origin of the noria is unknown, but it was certainly known in the Roman world and in China by the first century BCE. There is a possibility, therefore, that it was invented somewhere in the highlands of southwest Asia. The large noria at Murcia in Spain is still in operation, as are norias in various parts of the world, where they are often able to compete successfully with modern pumps.

Water wheels, as used in mills, were of three types: vertical undershot, vertical overshot, and horizontal. The first type was a paddle wheel mounted directly in a running stream. In the overshot wheel the rim was divided into compartments into which the water was directed from above, usually from an artificial channel or leat. Both vertical wheels required a pair of gears in order to transmit the motion of the water wheel to a vertical axle that led up to the millstones. In the horizontal type a jet of water from a reservoir was directed on to the vanes of the wheel, on the top of whose axle the millstones were installed. Various methods were used to increase the power and hence the output of mills. The wheel could be located in the piers of bridges or on boats moored on rivers, in both cases to take advantage of the increased rate of flow in midstream. In the Basra area in the tenth century there were mills that were operated by the ebb tide – about a century before the first mention of tidal mills in Europe. Apart from the production of flour from grains, water mills were also used for industrial purposes such as papermaking, the fulling of cloth and the crushing of metallic ores.

Bridges of all types were important in the Islamic world not only for communications but

also for protecting the banks of canals from damage due to fording people and animals. In the mountains of Central Asia, such as the Tien Shan and Hindu Kush ranges, both cantilever and suspension bridges were used for crossing ravines. The great rivers of Egypt, Iraq, and Transoxiana were usually crossed by bridges of boats. In many cases, however, rivers and other obstacles were crossed by masonry arch bridges built of dressed stone or, sometimes, especially in Iran, of kiln-burnt bricks.

Two bridges in western Iran, built in the tenth century, are constructed with pointed arches. This type of arch, which was to be such an important element in European Gothic architecture from the twelfth century onward, had appeared in Syria and Egypt during the seventh and eighth centuries, but only as a decorative feature. These Iranian bridges are the earliest known occurrence of the pointed arch as a load-bearing component.

Chemical technology was a highly developed profession in medieval Islam. The most important writer on the subject was Muḥammad ibn Zakariyyā ► [al-Rāzī](#). Although he wrote a number of alchemical books, his major work, *Kitāb al-asrār* (The Book of Secrets), written early in the tenth century, leaves us with the impression of a powerful mind, much more interested in practical chemistry than in theoretical alchemy. *The Book of Secrets* contains a comprehensive list of pieces of equipment, many of which are still in use today. The chemical processes described or mentioned by al-Rāzī include distillation, calcination, solution, evaporation, crystallization, sublimation, filtration, and amalgamation. Arabic works were undoubtedly an important influence upon the development of European chemistry. Evidence for this influence is the abundance of Arabic words in the chemical vocabularies of European languages. Examples in English are alkali, alchemy, alcohol, elixir, naphtha, and many others.

Mining played an important part in the economic life of the Islamic world. Spread throughout this vast area were mines for all the important metals, precious stones and essential commodities such as salt, coal and petroleum. The oilfields at Baku were exploited by the Muslims on a

commercial scale by the ninth century. In the thirteenth century Marco Polo reported that a 100 ship-loads could be taken from Baku at one time.

Iron and steel were, of course, the most important metals for many industrial and military purposes. Cast iron was described about 1040 by the great scientist ► [al-Bīrūnī](#) – it was exported to many countries as a raw material. There was also an extensive steel industry which produced, among other grades, the famous Damascus steel. As far as we can ascertain at present, this came from a number of Islamic centers in the Middle East and Central Asia. But it was certainly produced in Damascus itself.

We have been able to mention only the more important areas in which Muslim engineers and technologists were pre-eminent for several centuries. In many cases Islamic ideas were transmitted to Europe, but it is important not to evaluate Islamic technologies only with regard to their contribution to their European counterparts. Technologists in the Islamic world were responding to the needs of society and were extremely successful in a number of fields.

Technology in the New World

Aaron Segal

The indigenous peoples of the New World were excellent builders. Although their construction tools were limited they managed to produce pyramids, temples, and other public buildings in the Andean Highlands, the lowland jungles of Central America and the Yucatan, and the central highlands of Mexico. There were ceremonial ballcourts built throughout the Caribbean as well as in what is now Mexico, Guatemala, and Belize. Construction in North America included the mound sites of the Midwest and the Southeast and the cliff dwellings of the Southwest. While estimated populations at these sites varied from the hundreds to the thousands these were all urban societies and civilizations.

These master builders relied on their own concepts, designs, craftsmen, and techniques. In spite of claims of trans-Pacific, trans-African and other exogenous contacts, the evidence is sparse and less than convincing. The civilizations of the New World evolved on their own with only limited contacts with one another over space and time. Their achievements as well as their failure are entirely their own, including matters of technology.

The New World societies concentrated on identifying, applying, and improving instrumental technologies, whether for agriculture, irrigation, construction, crafts, or other utilitarian uses. The legacy that has survived is one of warrior-kings, royal courts, artisans cum farmers, priests and scribes, builders and artists.

The peopling of the New World began approximately 15,000 years ago when climatic changes made migration from Siberia and East Asia possible across the Bering Straits. It took another 8,000 years for these small wandering human bands to reach Patagonia and spread throughout most of Middle and South America. Somehow they managed to keep fertility above infant mortality as they diffused on foot

throughout the New World. Hunters and gatherers, they relied on stone age worked flint edges to kill, strip, and consume their prey. Their principal weapon, originating in Asia, was the *atlatl* or spear thrower improved with flexible sheets and stone weights. Bows and arrows were introduced later, also perhaps from Asia via the Arctic, and became a favorite weapon for hunting bison on the Great Plains. When the Tainos paddled island by island from Lake Maracaibo up the Caribbean Archipelago (A.D. 1000–1400) they were armed with an array of bows, arrows, stone, bone, and flint knives, *atlatls* and other weapons.

Those who undertook the Great Journey throughout the New World survived through environmental adaptation as they fanned out across two continents. Those who adapted to the Amazon Basin continued in a hunter-gatherer mode, learning the skills needed to survive in the tropical rain forest. The Arawaks, Tainos, and other voyagers to the Caribbean also relied primarily on hunting and gathering adapted to coastal fishing. Latecomers who remained in the Arctic or sub-Arctic turned to hunting, fishing, shelter, and other technologies to survive harsh winters.

Agriculture probably arose about 3000 B.C.E. simultaneously in the Andean highlands and Central Mexico, first as a supplement to hunting and gathering and as a response to growing populations. Gatherers observed which seeds yielded what plants and began to cultivate on a trial and error basis. Teosinte, a high-protein precursor of corn, was first cultivated in Mexico, while potatoes were an early ecologically suitable cultigen in the colder Andes. The list of cultivated edible plants soon expanded to include manioc, squash, peppers, pineapples, and other New World originals, especially several varieties of beans. The Tainos learned to grow tobacco and to cure it as snuff in their Caribbean islands, which became valuable trade items.

Agricultural technologies evolved to include the use of digging sticks, irrigation canals, terracing and ridging, intercropping, and seed beds. Lacking draught animals fires were set to clear new land. The most sophisticated technique was

that of the *milpas* practiced by the Aztecs who built silted mounds of fertile run-off materials.

Food processing and storage technologies were also innovated and widely diffused. The stone *metate*, or mortar and pestle, became the basic Mesoamerican tool for crushing corn. Ethnobotanical experience produced a variety of herbs, spices, and for the Mexicans chocolate to add to largely vegetable diets. As towns and cities grew, especially in the Andes and Mesoamerica, hunting declined in favor of limited domestication of chickens, turkey, pond fish, and small animals. However, animal protein was hard to come by in all the predominantly agricultural societies which relied on trade and food storage to supplement local corn, beans, manioc, and other staples.

Transport was a severe obstacle for all the New World peoples. Dogs were used to pull sleds and traverse with limited loads in the Arctic and on the Great Plains. Alpacas and llamas were semidomesticated and used for limited local transport in the Andes. However, everywhere terrain was rugged, surfaced roads were few and far between, and runners and head-loads were the primary mode of transport. Sailing vessels were unknown and the canoes of the Tainos and others had to hug shorelines for safety. Although the concept of the wheel was known, and toy wheels were used in the Andes, the lack of roads and the natural obstacles impeded the development of wheeled vehicles. The Spanish introduction of the horse and the cow revolutionized transport in the New World. Trade previously was confined to what could be carried on men's backs. Thus the Aztec long-distance traders, *pochotes*, specialized in high-value items such as jewelry, ceremonial feathers, and weapons.

Confined to limited home markets, New World societies tended to invest their agricultural surpluses in exquisite crafts. As royal courts developed around ceremonial centers so did specialized artisans capable of meeting quality demands, as well as items for daily use. The oldest discovered textiles date back 3,600 years to the Peruvian coast and were made of cotton with intricate woven designs. Dyed cotton for personal clothing became widely diffused with

pendants and ornaments often added. Excavation of Andean and other tombs has revealed the importance attached to clothing and jewelry and the high skills of the artisans. The Olmecs of the Mexican Southeast were the first to work in jade and turquoise as well as to create massive stone carvings. Metallurgy, especially in the form of masks, was highly accomplished in Mexico as well as among the peoples of what is now Costa Rica, Colombia, and Peru.

Ceramics and basket and gourd work were closely associated with the emergence of agriculture. Initial demands were for items used for carrying and storage. However, in the Andes and Mexico, as techniques improved, ceramics became an important ceremonial art form. Funerary jars, urns, water carriers, ceremonial masks, and other items are regularly depicted in sculptures and paintings and found in Aztec, Maya, and other tombs. Pre-Incan and Incan Andean societies also took pride in their varied and elaborate ceramics, baskets, and gourds.

Ceremonials were held largely outdoors, while palaces were for storage purposes. Most common people, including craftsmen, lived, ate, and slept in simple mud and brick dwellings. Their lords and masters lived in larger and more solid enclosures but with similar creature comforts. Building skills were directed at large-scale public constructions to honor the deities and/or fortresses for defense purposes. While kings lived in palaces with a few of their retainers many members of the court had to accept more humble accommodations. The benign tropical climate of the Caribbean contributed to nearly everyone's relying on hammocks and huts made of straw.

The Aztecs alone tackled the sewage and other waste disposal problems of man-made cities. They instituted barges along the canals of their capital at Mexico City, and also made an effort to keep water potable. At the Inca capital of Cuzco public hygiene was minimal as it had been in the Maya city-states. It may have been the scarcity of domesticated animals that reduced disease vectors in these highly crowded urban sites.

As builders the peoples of the New World concentrated their efforts on specific times and places. These included the Olmec

(1000–600 B.C.E.), Tectihuacan (A.D. 0–650), Toltec (1000–1300 B.C.E.), and Aztec (A.D. 1400–1530) civilizations in Mexico, the Mayas (A.D. 0–900) in Guatemala and Mexico, and the Moche (A.D. 0–600), the Nazca (A.D. 0–600), the Chimú (A.D. 1300–1420) and the Inca (A.D. 1400–1530) in Peru. They were able to construct magnificent and lasting buildings in environments as different as lowland jungles and highland mountains. They moved massive amounts of stone and carved and fitted it exactly with simple tools, as well as working with wood. Their architects designed vast open spaces and compelling interiors. Their multistory edifices reached up to the heavens, and served sometimes as astronomical observation sites, while commanding the world below. Their equivalents are neither the medieval cathedrals of Europe nor the Acropolis of Greece. Instead they are the most significant continuing testimony to the uniqueness of these New World civilizations and peoples.

While we can directly experience and marvel at these sites it is much more difficult to penetrate the intellectual worlds of their builders. The Mayas, prior to their collapse in A.D. 800–900, had a sophisticated writing system which was lost, as were many of their ideas about astronomy and mathematics. Similarly, the Nazcas of coastal Northern Peru who vanished around A.D. 600 may have had more advanced ideas about astronomy than their predecessors. The unevenness of historical experience and its inherently nonlinear nature is one of the sobering lessons of the history of science and technology in the New World. The Mayas alone invented a writing system which took nearly 450 years after the European Conquest to decipher. The Incas adapted a system of counting called the *quipu* for purposes of accounts and storage but never extended it into a mathematical base. The Aztecs excelled at urban planning, irrigation, and public health but showed little interest in writing.

The peoples of the New World were builders, agriculturalists, and craftsmen rather than scholars or theologians. The European conquerors came from an age of iron and steel with wooden ships, navigation, steel swords, guns, explosives, and literacy. They brought horses,

cattle, and smallpox, measles, diphtheria, trachoma, whooping cough, chicken pox, bubonic plague, typhoid fever, scarlet fever, amoebic dysentery, and influenza.

Telescope

Julian A. Smith

The telescope is an optical instrument used to make distant objects appear nearer and larger; it

consists of one or more tubes with a series of lenses, mirrors, or both (refracting, reflecting and catadioptric models, respectively), through which light rays are collected, brought to a focus, and magnified. Despite their great variety, all telescopes have two basic parts: the objective, which intercepts and focuses the incoming light, and the mounting, which supports the objective. The telescope, which revolutionized astronomical research in the seventeenth century, is usually considered to be a European invention, though parallel discoveries occurred elsewhere, and some of its elements were developed earlier by other cultures.

The traditional Western account of the telescope's invention is quite complex. The use of hollow sighting tubes without lenses to observe stars had been known to the ancient Greeks, being recorded by Aristotle (384–322 BCE) and the geographer Strabo (ca. 63 BCE–ca. 19 AD). Lenses are mentioned by the playwright Aristophanes (ca. 450–388 BCE), and mirrors were investigated by Heron of Alexandria (ca. 60 AD). The geometer Euclid (ca. 300 BCE) and the engineer Archimedes (ca. 287–212 BCE) studied both. The investigation of lenses, mirrors, and sighting tubes continued throughout the Medieval period. The invention of spectacles, an important telescope precursor, occurred between 1285 and 1300 by an unknown Italian glassmaker, but Alexandro della Spina (d. 1313) and his friend Salvino d'Armati (d. 1317) are most often credited. Meanwhile, English Franciscan friar Roger Bacon (1211–1294) wrote extensively of spectacles and other optical devices, and influenced many later scientists with his research into the laws of reflection and refraction.

An enormous number of sixteenth century figures developed various combinations of perspective glasses and mirrors to enlarge distant objects, including the English father and son surveying team of Leonard (ca. 1520–ca. 1571) and Thomas Digges (1546–1595), mathematician William Bourne (d. 1583), Italian natural philosopher Giambattista della Porta (1534/1535–1615), and Dutch mathematician Cornelius Drebbel (1572–1634). But the lack of

documentary evidence has thus far left historians divided over whether these instruments were true telescopes or just magnifying glasses.

The first unambiguous accounts of the European telescope come from Holland around 1608. Most credit the Middleburg spectacle maker Hans Lippershey (ca. 1570–1619) with the first refracting telescope; but there are rival claims by Middleburg optician Zacharias Jansen (1580–ca. 1638), and Alkmaar inventor Jacob Metius/Adriaanzoon (1571–1635).

Early telescopes were first applied to military operations. But over the winter of 1609–1610, Italian physicist and astronomer Galileo Galilei (1564–1642) dramatically improved Lippershey's primitive device and turned it to the sky. His announcements of lunar valleys and mountains, sunspots, the phases of Venus, the moons of Jupiter, and much more (published in the March, 1610 *Sidereal Messenger*) thoroughly shook the ancient earth-centered cosmology of Alexandrian astronomer Claudius Ptolemy (ca. 150 AD). Similar observations were made between 1609 and 1612 by English polymath Thomas Harriot (1560–1621). The word "telescope," meanwhile, was coined in 1611, and was first printed in Julius Caesar Lagalla's (1576–1624) *Lunar Phenomena* of 1612.

Early Galilean telescopes, with one biconvex and one biconcave lens, suffered from both chromatic and spherical aberration, which left blurry images. The German astronomer Johannes Kepler (1571–1630) designed the improved Keplerian telescope of two biconvex lenses in 1611, but problems remained. It was not until 1636, when the Minorite friar Marin Mersenne (1588–1648) suggested replacing lenses with mirrors, that real progress could be made. Reflecting telescopes were designed by Scottish mathematician James Gregory (1638–1675) in 1663, and built a few years later by both Isaac Newton (1642–1727) and French physicist Guillaume/Nicholas Cassegrain (fl. 1672); these models (Newtonian and Cassegrain) are still widely used today.

During the period 1610–1650, the telescope was carried by European explorers to all regions of the earth; frequently Jesuit missionaries

exported it to non-Western cultures. However, there is evidence that other societies developed both the telescope and its various parts independently of Europe. Glass originated in Egypt about 3500 BCE and was first produced on a large scale by the Phoenicians, and lenses dating back to pre-Greek times (2000 BCE) have been discovered in Crete and Asia Minor/Mesopotamia.

Meanwhile, Arabic astronomers played a significant role in paving the way for the telescope. The mathematical laws of optical reflection and refraction in glass and other media were thoroughly investigated and extended by the physicist-astronomer Ibn al-Haytham (Alhazen, 965–ca. 1040). Ibn al-Haytham knew how to use spherical glass segments to magnify objects, and was familiar with spherical aberration and techniques to calculate the focal lengths of lenses and mirrors. Much of this knowledge was subsequently transmitted to Europe through Latin editions of his work, and especially through the texts of his Polish disciple, Witelo of Silesia (ca. 1230–ca. 1275). Bacon also learned much from Ibn al-Haytham.

Sighting tubes were also early employed by Arabic astronomers; ► [al-Battānī](#) (858–929) used them in his Raqqa observatory. ► [Naṣīr al-Dīn al-Tūsī](#) attached one to a sextant at his Maragha observatory in 1259 to study the sun.

Meanwhile, Needham argues that Chinese opticians may have discovered the elements of the telescope either before, or parallel to, the Europeans. Though glass was developed fairly late (ca. 500 BCE), quartz rock-crystal had been in use since ancient times and lenses of both materials were employed to focus solar rays to start fires. Needham also claims the Chinese used smoky rock-crystal to observe sunspots and eclipses. An important text of Tan Qiao (the *Hua Shu* or Book of Transformations of about AD 940) records the use of planoconcave, planoconvex, biconcave, and biconvex lenses to make objects larger, smaller, upright, and inverted. Spectacles have often been considered a Chinese invention, but this is based on a garbled text; they were brought overland from Europe by 1300. As for catoptrics, Mohist opticians of the

fourth century BCE studied both concave and convex mirrors, and were familiar with real and inverted images, focal points and refraction in different media. The use of concave mirrors to ignite tinder by focusing sunlight goes back to the Chinese Bronze Age; one of the earliest citations is dated 672 BCE.

Chinese sighting tubes made of ► [bamboo](#) are similarly old; the most important early reference is the (approximate) sixth century BCE *Shu Jing* (*Historical Classic*). By the *Huiai-Nan Zi* (*Book of Huai-Nan*) of 120 BCE, they were widely used in land surveying and triangulation; and by the twelfth century, they were standard navigational equipment for taking astronomical observations aboard ships.

Though many of these developments were contemporaneous with European discoveries, there are two parts of the telescope in which Chinese scientists can claim undisputed priority: the invention of equatorial mounting, and the development of clock drives, both of which are standard equipment on today's telescopes.

Astronomer Guo Shoujing (fl. 1270) developed the equatorial mounting now used on all modern telescopes for his “simplified instrument”, which was basically a dissected armillary sphere related to the torquetum, an Arabic invention which had been recently imported (ca. 1267) to China from Persia. With an equatorial mounting, a rotation about only one axis (one parallel to the earth's polar axis) was needed to follow the curved paths of the stars.

Chinese physicists and engineers anticipated the fourteenth century mechanical clocks and clock-driven astronomical instruments of Europe by over a 1,000 years. Mathematician, geographer and astronomer Zheng Heng (ca. 78–ca. 142) constructed what Needham calls the “grand ancestor of all clock drives,” a rotating bronze armillary sphere powered by a system of gears attached to a waterwheel. This device was used to predict the positions of various stars and planets. The later clock-driven armillary sphere of Su Sung (AD 1090) added a sighting tube to permit direct observation of a star as it moved over prolonged periods, resulting in a true “clock drive” for astronomy.

But despite Chinese priority in clockwork and mounting, just as in Europe, it was not until the seventeenth century that the disparate elements of the telescope were joined together. Though Chinese texts describe European telescopic discoveries from 1615 onwards, and Jesuit Father Terrentius/Johannes Schreck brought a telescope to China in 1618, Needham maintains that enough documentary evidence exists to assert a parallel, independent discovery by Suchow opticians Po You and Sun Yun Qiu. Between about 1620 and 1650, this pair constructed not only early telescopes, but also compound microscopes, magnifying glasses, searchlights, magic lanterns, and other instruments. Meanwhile, Sun Yun Qiu wrote a text on these and other optical devices, entitled *Jingshi (History of Optick Glasses)*. But the first Chinese book on the telescope specifically was the *Yuan Jing Shuo (Far Seeing Optick Glass)* of Tang Ruo-Wang (Adam Schall von Bell) in 1626. *Yuanjing* became the standard term for the telescope, and by 1635 it was being widely used by Chinese artillery in battle.

Telescopes appear to have come to Indian astronomers fairly late. Indian craftsmen made glassware, lenses, and mirrors throughout the ancient and medieval periods. And *gola yantra* or armillary spheres, first mentioned in the *Āryabhaṭīya* of Āryabhaṭa I of Kusumpura (b. 476 AD), had clock-drives (powered by clepsydra) for stellar observation by the *Bhatadipika* of Parameśvara (ca. 1432).

But it was not until the seventeenth century that primitive telescopes were used in India. The celebrated astronomer and instrument-maker Sawai Jai Singh (1686/1688–1743) employed telescopes to “show that Mercury and Venus get their light from the Sun as the Moon does” (*Zica-i Muhammad Shahi*); and though they revealed Saturn to be an irregularly shaped “oval,” these telescopes were apparently not good enough to resolve the rings, which had already been accomplished by Dutch physicist Christiaan Huygens (1629–1695) several decades previously, in 1659. Indian achievements in this area thus far appear to be rather derivative, but much research still needs to be done in this area.

Temples in Ancient Egypt and Archaeoastronomy

Mosalam Shaltout

Solar and Space Research Department, National Research Institute of Astronomy and Geophysics (NRIAG), Helwan, Cairo, Egypt

During the last 5 years, the Egyptian-Spanish Mission on ancient Egyptian astronomy and

archaeoastronomy, conducted under the auspices of the Egyptian Supreme Council of Antiquities, has been performing an ambitious scientific project with the aim of studying the cosmovision of the ancient civilization of the pharaohs. Part of the project consists of a reanalysis of the iconographic and historical sources that has allowed a reassessment of the calendar theory (Belmonte, 2003), challenging old-fashioned paradigms, or a new proposal for the sky maps of ancient Egypt (Lull & Belmonte, 2006).

However, the most expensive part of the project, in time, effort, and resources, has been the five campaigns devoted so far to measuring the orientation and studying the spatial location of ancient monuments across the Nile Valley and beyond. More than 500 pyramids, hypogea, chapels, sanctuaries, or small and large temples have been measured so far. The fieldwork in successive campaigns was organized geographically but also with the intention of testing previous results with new exercises. Four papers have been published about the temples in which we

have analyzed the relation of temple orientation and their location within the local landscape, understanding landscape in its broadest meaning of both terrestrial (basically the Nile) and celestial (astronomical orientations) aspects. Our studies demonstrate that both components were necessary and intimately correlated.

Figure 1 shows the location of the sites where we have assembled the data of the temples along the five campaigns. We have taken measurements in almost every archaeological location within Egypt. These include very well-preserved temples, such as the one of Horus in Edfu, or monuments where just a few walls of the foundations were visible. The orientation has always been taken from inside looking outside, from the sanctuary of the temple to the gate, seldom across several halls, courts, and pylons. In a few occasions, the opposite direction has also been considered or even the perpendicular to the main axis.

We were not seeking extreme-precision alignments. Our main task was to measure as many

Temples in Ancient Egypt and Archaeoastronomy,

Fig. 1 Map of Egypt showing the location of sites, from the Western and Eastern Deserts to the Nile Valley, where the orientation data yielded by our five field campaigns have been assembled. Dots stand for sites with just one or a few (two or three) sanctuaries on site. Ellipses stand for imposing archaeological sites where several temples, sometimes as much as ten, could be measured within a single location

sacred buildings as we were able to, giving a similar weight to those exceptionally well preserved and to temples where not more than a few walls are visible. We obtained our measurements using a high precision compass, correcting for local magnetic declination which is not expected to suffer alterations in Egypt, mainly a limestone and sandstone land, and a clinometer, both as isolated instruments or enclosed within a single tandem device. The instruments permit a theoretical 0.25° precision for both kinds of measurements. However, owing to various considerations, an error close to 0.5° in both azimuth and angular height is probably nearer to reality. This would signify a mean error of order $\pm 0.34^\circ$ in the determination of the corresponding declination. For the latitudes of Egypt, a precision of 0.5° is perhaps the best we can expect in solar, lunar, or very bright star observations near the horizon, and in the case of fainter stars, the errors in estimating the azimuth can range from more than one to several degrees. We consider our altazimuth data to be of good enough quality to pursue our main quest, i.e., to demonstrate the importance of certain families of astronomical alignments in ancient Egypt.

Testing Nile Orientations: The Null Hypothesis

The majority of Egyptologists have traditionally considered ancient Egyptian temples to be orientated with respect to the Nile. On several occasions, this preconceived notion has precluded any serious or systematic attempt on the part of the Egyptological community to study the orientations of the temples, and most efforts up to a few years ago had come from dedicated archaeoastronomers, like Hawkins (1973) or Krupp (1988), whose conclusions were not always assimilated. Indeed, we have heard this opinion several times, even being asked by some reputed scholars why we were devoting so much effort to a question that was crystal clear. So, from the very beginning of our project, one of our primary objectives has been to test the Nile hypothesis in order to check if so many scholars

could be wrong. We demonstrated that they were indeed correct and that in Upper Egypt the Nile was the main source of inspiration for orientating sacred buildings, but that it was not the only one. We tried to falsify the Nile hypothesis by performing fieldwork in a land with no river, the oases of the Western Desert, and we found that when the Nile is absent, astronomical orientations certainly dominate the situation. Figures 2 and 3 repeat those exercises but with a larger amount of additional data obtained in later campaigns.

Figure 2 shows a histogram where the difference between the orientation of the temple and the course of the Nile versus frequency is presented. The histogram has been produced with the data of 170 temples in Upper, Middle, and Lower Egypt, with the particularity that in the Delta the difference is with respect to the closest river branch. The plot clearly demonstrates that temple orientation with the main gate located in front of (axis perpendicular to) the Nile is the most common way of orientating the buildings. Furthermore, axes nearly parallel to (at $\sim 0^\circ$ or 180°) or perpendicular to the river, but facing the other way ($\sim 270^\circ$), were also common. This demonstrates beyond any reasonable doubt that local topography (the course of the Nile) was very important at the moment of settling the foundations of the temples.

In contrast, Fig. 3 shows the orientation diagram of 95 temples in the deserts and oases of Egypt, where there is no river to justify the orientation. The diagram shows the typical form of a Maltese Cross which is probably related to a certain preference for solar and cardinal orientations that could not be obtained without a celestial reference. The answer to the controversy is fascinating, as both hypotheses should be correct. This is what we have seen during these years and demonstrated in previous works on the topic. Even more, we are almost convinced that certain places throughout Egypt had an especially sacred character because they presented double (topographic and astronomical) alignments, such as Karnak or Denderah, and some customs, like the selection of cardinal or quarter-cardinal orientations in certain regions, would follow a similar line of reasoning.

Temples in Ancient Egypt and Archaeoastronomy, Fig. 2 Testing the Nile hypothesis. Histogram representing the difference in orientation between the main axes of 170 temples of the Nile Valley and the average course of the river (or river branch in the case of the Delta) at their corresponding locations, for an interval of $\pm 1^\circ$, larger than our estimated error of $\frac{1}{2}^\circ$, allowing for probable historical changes in the river flow. Temple orientation with the main gate located in front of (axis

perpendicular to) the Nile is the most common way of orientating the buildings. Axes parallel to (at $\sim 0^\circ$ or 180°) or perpendicular to the river, but facing the other way ($\sim 270^\circ$), were also common. This demonstrates beyond any reasonable doubt that local topography (the course of the Nile) was very important at the moment of settling the foundations of the temples but was not the only factor to be considered. See text for further discussion

Temples in Ancient Egypt and Archaeoastronomy, Fig. 3 Falsifying the Nile hypothesis. Orientation diagram of the data assembled for temples measured outside the Nile Valley, where the river influence should be absent. Notice the Maltese Cross form of the diagram typical of astronomical orientations with a preference for cardinal and solar orientations

Challenging New Hypotheses: Astronomy in Action

During our campaigns, we tried to measure as many monuments as we were able to, in an attempt to put at our disposal as much statistical weight as possible. The idea was to put an end to the controversy about the question of whether the Egyptian temples were astronomically orientated or not. The results of the experiment are presented in Fig. 4 and are very suggestive. As a matter of fact, 11 peaks are significant in the plot and we believe that they correspond to seven possible different families of astronomical alignments of Egyptian temples. These could be classified as follows (same Roman numbers as in Fig. 4):

- (I) **The eastern (or “equinoctial”) family.**
The peak corresponds to a declination of $-1^\circ \pm 0.34^\circ$. This suggests an orientation to the equinoctial sun when the disk has

Temples in Ancient Egypt and Archaeoastronomy, Fig. 4 The core of the astronomical hypothesis. Declination histogram of some 330 temples of ancient Egypt obtained from the data measured in our five field campaigns across Egypt and their analyses as presented in Papers 1, 2, 3, and 4. Each peak is identified by a Roman numeral referring to each of the seven families of astronomical orientations as defined in Paper 3 and explained in detail in this work. Only peaks with values of the

frequency above the average (*dot line*) have been taken into account. Long-dashed lines stress the extreme and medium positions of the sun at the solstices and equinoxes, respectively. The lines for Sirius (*dot dashed*) and Canopus (*short dashed*) straddle the extreme declinations of these stars, the brightest ones of the skies of ancient Egypt, from the beginning to the end of her civilization. See the text for further discussion

completely risen above the horizon. This might imply that the ancient Egyptians were able to determine the day of the equinoxes with a reasonable precision. Another solution is that this family could be the result of an orientation in the Meridian line (probably to due north), and later the gate of the temple would have been open by establishing the perpendicular through standard topographic techniques. The pyramid complexes could be the paradigmatic example of such a procedure (see Fig. 5), where the N-S axis of the pyramid would have been the first element of the construction obtained in the foundation ceremonies (Belmonte, 2001; Spence, 2000). We can find arguments in favor of one or other alternatives, and the probable solution is that both kinds of monuments ought to be included within the group. These would include “equinoctially” orientated

monuments, such as the Sphinx or the solar temples of the 5th Dynasty at Abo Ghuorb, and 90° rotated axis temples such as those of the pyramid complexes of the Old and Middle Kingdoms.

- (II) **The solstitial family.** With a peak at $-24^\circ \pm 0.34^\circ$, this group is dominated by a series of temples orientated to sunrise at the winter solstice, although other solstitial orientations have also been documented. This is the dominating astronomical custom in the temples of Upper Egypt (see Paper 1 and Fig. 6) and was also found at many other locations within Egyptian geography. On the one hand, there has been discussion relating to the importance of the winter solstice with respect to the extended Mediterranean idea that the birth of the Sun happened exactly as this solar time mark. On the other hand, the summer solstice could have been important in

Temples in Ancient Egypt and Archaeoastronomy, Fig. 5 Schematic diagram where we show the astronomical and topographical relations between the different monuments erected in the Giza Plateau, notably the Sphinx and the pyramids, and certain elements of the sky or nearby geography. The relation with Letopolis and Heliopolis was first proposed by Goyon (1970). However, in this diagram, we additionally relate the original northern orientation of the pyramids, based on the observation of *Meskhetyu*'s Meridian transit (Belmonte, 2001), and the

similar name of the province which had the Letopolis as capital, the Bull's Foreleg. Astronomical connections of the Sphinx with equinox sunrise and summer solstice sunset (behind *Akhet Khufu*, the Horizon of Khufu, see Paper 3) are also stressed. However, another possible astronomical connection between the Sphinx and winter solstice sunset at the SE corner of Menkaure's pyramid (*dot line*) needs further evaluation (Photographs by Juan A. Belmonte)

ancient Egypt as a date close to the average arrival of the inundation. Besides, it has been argued that this time marker could be closely related to the origin of the 365-day civil calendar. Associated to this family, we have the peculiar $\Pi \perp$ peak. We are convinced that this group of temples, orientated to an interval of declinations centered at nearly 54° , includes monuments whose axis was obtained by rotating

90° anticlockwise, a previous orientation determined by winter solstice sunrise.

- (III) **The seasonal sun family.** This group of temples corresponds to monuments orientated to a peculiar interval of positive and negative declinations of $11.5 \pm 0.5^\circ$ and $-11^\circ \pm 0.34^\circ$, peaks III+ and III-, respectively. We speculate that this family had also a solar origin. One of the most interesting cases in this family is that of the

Temples in Ancient Egypt and Archaeoastronomy,

Fig. 6 Sunrise at the winter solstice in the main axis of the temple of Karnak. The phenomenon would have been more accurate 4,000 years ago when the temple was first aligned. This huge complex of temples was located at one of the few places in the Egyptian geography where the solstitial line, connecting winter sunrise and summer sunset, was at the same time perpendicular to the Nile. Solstitial orientations were very frequent in ancient Egypt, perhaps reflecting the importance of the solar cult in a way that we do not fully understand yet but that we are starting to envisage (Photograph by Juan A. Belmonte)

temples of Aton at Tell el-Amarna. One of these temples is clearly orientated to a distinctive notch on the eastern horizon similar to an *akhet* sign. Actually, it has been suggested that this geographical accident gave its name to the city, *Akhetaten*, the Horizon of Aton. Since the main gate of the temple is, at the same time, perpendicular to the Nile, the orientation and location of the temple of Aton could have simply been dictated by topographic features. However, there is a striking additional possibility. Sunrise at the *akhet* would have occurred on dates close to October 22 and February 20. Surprisingly, or not, these dates are similar to those when the famous sun-illuminating phenomenon occurs at the great temple of Abu Simbel (Fig. 7). For Abu Simbel, we have proposed a relation to the beginning of two of the seasons of the Egyptian calendar, *Peret* and *Shemu*, “Going Forth”

and “Drought,” respectively. In the reign of Akhetaten (c. 1352–1336 B.C.), the seasons of the calendar did not exactly correspond to the climate seasons (although this happened for Ramses II). However, these dates still divide the year in two periods, one of 120 days (exactly four Egyptian months of 30 days, or one calendar season) and another of 245 days, and they might have acted as harbingers of the real sowing and harvest seasons, respectively. Another temple complex of this family would be the sanctuary of the sun-god Re at Heliopolis, and as a matter of fact, it would be logical to expect a solar-related orientation for it. Hence, we have finally proposed the hypothesis that this group of temples would actually integrate a so-called seasonal sun family of orientations, with possible members all around Egypt. In fact, the “solstitial family” could be interpreted as a more specialized subgroup of this.

Temples in Ancient Egypt and Archaeoastronomy, Fig. 7 A diagram expressing the probable relation between the Egyptian calendar and the temples of Abu Simbel. On the one hand, the minor temple, dedicated to Queen Nefertari in her *Sopdet* dressing (upper right image), would be related with the heliacal rising of this star and the arrival of the inundation (although the temple is not orientated in the adequate manner), a coincidence

occurring for a period of years during the reign of Ramses II at the precise location of the temples. On the other hand, the splendid hierophany of the well-known solar illumination phenomenon in the sanctuary of the major temple (lower right image) would occur at the eve of the other two seasons of the civil calendar, the 1st day of the month of Thibi and the first of Pachon, respectively (Photographs by Juan A. Belmonte)

(IV) **The *Sopdet* family.** The main peak of this family would correspond to a declination of $-17.34^\circ \pm 0.34^\circ$, covering most of the period of the Middle and New Kingdoms. The star *Sopdet*, our Sirius, the brightest star of the ancient Egyptian skies, was very important as the harbinger of the actual flooding at least from the Middle Kingdom onwards, when the phenomenon of its heliacal rising (*Peret Sopdet*) is mentioned in the hieroglyphic texts on several occasions (Belmonte, 2003), although its name is also largely mentioned in the Pyramid Texts within the context of the stellar scatology of the Old Kingdom (Faulkner, 1969). This family of orientations would also have representatives all over Egypt.

(V) **The Canopus family.** With a peak at $-53.34^\circ \pm 0.34^\circ$, this stellar interpretation of this family is far more complicated because we cannot prove the importance of Canopus for the ancient Egyptians, notwithstanding the fact that it was their second brightest star in the sky (Allen, 1963). Canopus changed its declination from -56.25° to -52.5° during the course of Egyptian history and would adequately fit the data. However, in our present state of knowledge, we do not know how to justify this relation either from the religious, economical, or social point of view, in contrast to the case of *Sopdet*, which played a major role in Egyptian culture.

(VI) The Meridian (or northern) family.

With two major peaks, VI+ and VI–, located at declinations of $60^\circ \pm 0.34^\circ$ and $-61^\circ \pm 0.34^\circ$, respectively; these “peaks of accumulation” clearly speak of the great importance of near Meridian, not to say precise N-S, orientations in ancient Egypt. In fact, it is highly probable that families I and VI are the two sides of the same coin. Indeed, both are representative of the predominance of cardinal orientations according to the manner in which the

ancient Egyptians organized the cosmos. We support the idea that this northern custom was effectively achieved through orientations to certain configurations of stars near the celestial pole and that the circumpolar constellation of *Meskhetyu* would be the most appropriate target for this purpose (Belmonte, 2001) as shown in Fig. 8. *Meskhetyu*, the Plough, undoubtedly was one of the most important asterisms of Egyptian religion since at least the Old Kingdom, if not earlier, where it appears

Temples in Ancient Egypt and Archaeoastronomy, Fig. 8 The simultaneous Meridian transit (a particular astronomical configuration) of two stars of *Meskhetyu* (the Plough), notably *Megrez* and *Phecda*, as the possible reference for the northern orientation of three singular monuments pertaining to different periods of Egyptian history. (a) Predynastic structure HK29A at Hieraconpolis (Kom el Ahmar). The original north alignment was later rotated 45° clockwise so that this early sanctuary would also be almost perpendicular to the Nile at this particular

spot (family VII). (b) Precise N-S orientation of the minor step pyramid of King Snefru at Seila, in the heights to the east of the oasis of Faiyum. This procedure could have been followed to accurately orientate the pyramids of the 4th Dynasty for many generations (Belmonte, 2001). (c) The same case as (a) but almost 2,000 years later for the Osireion of the temple of Seti I in Abydos. Notice the displacement of the azimuth of the simultaneous transit versus time caused by precession

in the Pyramid Texts as the “imperishable star,” to the Ptolemaic Period when it is profusely mentioned in connection to temple orientation.

- (VII) **The family of quarter-cardinal directions.** This family is related to a peak located at a declination of $-39^\circ \pm 0.34^\circ$ (VII-) and asymmetric at some 40° (VII+). It would be defined by those temples with an orientation close to the SE-NW and SW-NE lines, and we believe that it is a subgroup of the cardinal superfamily. It is our contention that this orientation was achieved by the primary determination of a north alignment, which axis was later rotated by either 45° or 135° clockwise for temples open to the east side of the horizon, which are the most frequent, or anticlockwise for temples open to the west side of the horizon. By performing such an action, simultaneous astronomical and Nile orientations could be achieved in several cases. Some of the Million Year Temples of kings of the New Kingdom, especially in Abydos and Western Thebes, are good representatives of this group. However, the oldest temple excavated so far, whose plan has been partially recovered, structure HK29A at Hieraconpolis, would be the earliest example of the class (see Fig. 8).

In summary, by defining these seven families, we hope to have shown the importance of astronomical orientations in ancient Egypt. By analyzing the previous paragraphs, we might reach the conclusion that actually only three customs of astronomical orientations were present in ancient Egypt: cardinal (i), solar (ii), and stellar (iii).

- (i) The cardinal custom would be integrated by families I (in most occasions), VI, and VII and would be achieved by the observations of certain configurations (rising, setting, Meridian transit, maximum elongation, etc.) of stars in the north, predominantly, if not exclusively, stars of *Meskhetyu*. This procedure would initially give a near Meridian axis that would later offer various alternatives:

a gate opening north, a gate opening south, a gate opening east (or west), or a new axis by turning the original by 45° or 135° , with the gate opening near NE (or NW) or SE (or SW), respectively.

- (ii) The solar custom will be formed by families I, II, II $\perp$, and III and would basically be related to important points of the annual cycle of the seasons, or in some cases to special dates in the civil calendar such as *Wepet Renpet*, Egyptian New Year's Eve, or the eves of the other two seasons *Peret* and *Shem*. Paradigmatic examples would be the solar temple of Niuserre at Abu Ghurob (I), Karnak (II and II $\perp$), and Abu Simbel (III).
- (iii) The stellar custom would be represented by families IV and V. We have no doubts of the pertinence and relevance of the alignments to *Sopdet*. However, we have minor doubts if any of the presumable alignments to Canopus should be interpreted in a different way. In this case, it is difficult to see how new field data will provide a final answer. Hence, new epigraphic information confirming the importance of this bright southern star would be highly desirable.

A final point to discuss is how once an alignment was yielded by astronomical observations in a certain direction (e.g., Meridian or solstitial ones), the new axis at 45° , 90° , 135° (in both clockwise or anticlockwise directions), or 180° was obtained. The answer to this question could be encountered in a recent hypothesis (Miranda et al. 2008), which suggests that the sign of Seshat (the divinity mostly involved in temple orientation ceremonies, notably the stretching of the cord), carried by the goddess upon her head in all representations, might perhaps have been a schematic and symbolic representation of an archaic transit instrument that would have later become the emblem of the goddess. This instrument would have had eight radii and a viewpoint and could have been used at the “stretching of the cord” ceremonies since the dawn of Egyptian history, directly offering the eight directions under discussion from a single astronomical or topographical observation.

Conclusions

We wanted to demonstrate if the temples of Egypt were astronomically orientated or not. Epigraphic sources clearly mentioned solar and stellar targets as the references for temple orientations. However, the scientific community only agreed on the planning of orientations according to the Nile, and the relevant inscriptions were sometimes considered as mere remembrance of long forgotten practices. We have now measured 330 temples and shrines. This represents approximately 95 % of all the temples in any state of preservation still existing in the country, and our sample is statistically significant.

We want to stress a few results that are highlights of the analysis of the complete series of data, which should change the mind of the specialists with respect to Egyptian archaeoastronomical studies. These are:

- (i) The temples of the Nile Valley and the Delta were orientated according to the Nile as our data have clearly illustrated, but . . .
- (ii) The temples were also astronomically orientated beyond any reasonable doubt as all the successive analyses we have done to our data fully demonstrate. This means that the ancient Egyptians had to deal with special situations to accomplish both necessities. This problem was solved by the selection of appropriate orientations of one or the other class at different sites so that they would be more or less compatible with the Nile course (quarter-cardinal directions are a good example of this), or by the deliberate election of selected places in Egypt where the Nile prescription and a conspicuous astronomical orientation were simultaneously achieved, as in the case of the temple of Karnak.
- (iii) Among astronomical orientations, there were three kinds of targets. One was probably related to different celestial configurations of the stars of *Meskhetyu* in order to get a near or accurate Meridian orientation. This primary axis could have been rotated later by an eighth, a quarter, or half

a circumference to obtain any possible cardinal or quarter-cardinal direction (families I, VI, and VII). The second kind of target had a markedly solar character and was fundamentally related to important time marks of the annual cycle and/or the civil calendar (families I, II, II $\perp$, and III). Finally, the third group of targets was formed by the two brightest stars of the ancient Egyptian skies, Sirius and Canopus (families IV and V, respectively). These customs were present during most of Egyptian history and in different areas of the country, although some minor interesting peculiarities have been discovered.

At the turn of the century, the authors envisaged a project to answer a quite simple question. Were the ancient Egyptian temples astronomically orientated? Now, a few years later, we are proud of the quantity and variety of the results we have obtained. These have been the gateway for new questions. Indeed, much more work could be done. However, we consider our sample to be statistically representative, and we are convinced that new data will only serve to reinforce our results. This summary article clearly illustrates something that we could only have imagined at the very beginning of our project: ancient Egyptians undoubtedly scrutinized the sky in a permanent search for their correct orientation not only in time but also in space in a permanent effort to keep Ma'at on Earth.

Temples of the Maya

Megan E. O'Neil

Department of Art History, Barnard College,
Columbia University, New York, NY, USA

When Spanish Christian friars arrived in the Yucatan Peninsula in the sixteenth century, they saw Maya people in towns comprised of buildings where people lived and worshiped. In *Relación de las Cosas de Yucatán*, Fray Diego de Landa recounted the performance of New Year ceremonies at the cardinal directions with the purpose of renewing the community and the world (Taube, 1988, pp. 298–299; Tozzer, 1941, pp. 135–150). Such descriptions provide useful information for reconstructing Maya religious use of space in the sixteenth century and earlier,

but these commentaries are limited and biased by the writers' worldviews and desires to convert Maya people to Christianity. Over the course of subsequent centuries, new understandings of Maya temples have come to light. Archaeological excavations have exposed myriad structures and associated artifacts, epigraphic research has deciphered inscriptions about politics and religion, art historical analyses have shed light on Maya imagery, and ethnographic studies, as well as collaborations with Maya people, have deepened our understandings of Maya religion and society. Together, these forms of analysis and interpretation have revealed a wealth of new information about the physical qualities and symbolic values of ancient Maya temples.

Temple forms changed over the course of pre-Hispanic Maya civilization, but there also was remarkable continuity in the purpose and design of temples and associated imagery. Images and texts on temple exteriors frequently identify what the temples commemorate, marking them as mythological places and houses of gods and ancestors. Indeed, many convey that Maya temples were dedicated to deities (personifications of natural phenomena such as sun, rain, and corn) and revered ancestors (generally male rulers or queens), some who had merged with deities upon death.

Scholars organize Maya chronology into periods called the Late Preclassic (200 BCE–200 CE), Early Classic (200–600 CE), Late Classic (600–900 CE), and Postclassic (900–1521 CE) for the lowlands of southern Mexico, northern Guatemala, Belize, and western Honduras. Based on terms used for Classical Greece, this chronology was developed in the mid-twentieth century, when the Maya Classic period was understood as the florescence of civilization, with periods before deemed formative and those after characterized by decline (Proskouriakoff, 1950). Nonetheless, subsequent discoveries and analyses have demonstrated remarkable innovation and indeed florescence of art, architecture, and other aspects of civilization in all periods, most notably in the Preclassic, whose remains are continually being uncovered in new excavations across the Maya realm (e.g., Taube, Saturno, Stuart, & Hurst, 2010).

Temple architecture – and Maya architecture in general – emphasizes both mass and open space (Miller & O’Neil, 2014, p. 46) (Fig. 1). The Maya frequently modified landforms and added fill to construct massive platforms upon which they built structures interspersed with plazas and courtyards, where both religious ceremonies and mundane activities took place. From the Late Preclassic to the Postclassic, builders constructed large pyramids, usually with terraced bases, that generally were solid but inside held tombs, offering caches, and remains of earlier structures (Fig. 2). Atop the pyramids were superstructures with one or more relatively small rooms. The size and shape of the superstructures are based on the traditional Maya house, which had thick lower walls made of wattle and daub and a thatched roof. Like the Maya house, temple superstructures frequently have one central doorway, usually with a wooden or stone lintel spanning the portal, though some have multiple doorways. Temple rooms are formed by corbel vaulting, whose arched interiors recall the pitched roofs of Maya houses (Fig. 3). Corbel vaults set parallel to each other allowed for multiple interior chambers and increased structural stability. Maya temples also could be single-story constructions that were set onto a platform.

Most pyramids had a central stairway, and some had stairways on multiple sides; the radial

pyramid, seen both in Preclassic Uaxactun and Postclassic Chichen Itza, had a central stairway on all four sides of the pyramid. These stairways gave access to shrines and also were places for processions and other performances. Indeed, the wide stairways of platforms and pyramids, in addition to the open plazas near temples, were essential spaces for Maya ritual performances, complementing the much smaller spaces of interior sanctuaries.

Pyramids were intentionally made large, certainly to emulate mountains, but the sizeable masses also grew over time with the accrual of construction layers, for which earlier structures were buried inside later ones. The presence of the earlier remains, particularly from named ancestors, gave additional significance to these buildings, ideas made explicit through inscriptions placed on later buildings, such as Copan’s Hieroglyphic Stairway (Structure 26), which was constructed over earlier buildings and whose stairway bears a lengthy text recounting centuries of dynastic history (Fash, 1998; McAnany, 1998) (Fig. 4). Such temples commemorate not only the latest structure and its patron but also the earlier structures and ancestors whose remains the building subsumes. Examples of large, layered buildings related to dynastic commemoration appear in Tikal’s North Acropolis, Copan’s Acropolis, and Uaxactun’s A-V platform (Fash, 1998).

Temples of the Maya, Fig. 3 Corbel Vault in Palace House A, Palenque, Mexico (Photograph by author, © Megan E. O'Neil)

Temples were oriented to plazas and other buildings, and they also were often built in relation to natural features such as mountains, caves, and water sources such as springs and *cenotes* (natural sinkholes). Furthermore, at times they were oriented to celestial bodies such as the sun and Venus on particular days of the year, such that doorways or windows frame the celestial bodies' presence in the sky or direct their light into the building (e.g., Tate, 1992, pp. 111–115). Indeed, temple engagements with natural phenomena were an inherent part of their symbolic value and the experience of these structures on a daily basis or on special days (Fig. 5).

Maya masons used locally available materials such as limestone, sandstone, and volcanic tuff for the construction of platforms, walls, piers, and lintels, though at Comalcalco, Mexico, they used clay bricks instead of stone. Across the Maya region, builders also used wood for beams and lintels. Exterior terraces and walls usually were covered with stucco, made by mixing crushed burned limestone with vegetal gums and water, for smoothing and decorating surfaces.

The stucco was often painted with mineral pigments in solid colors, such as hematite for a deep red hue, or with polychrome figural murals (Figs. 6 and 7). The Maya also created high-relief sculptures out of stucco and stone mosaic on

temple exteriors. Roof combs, which were erected on top of the corbel vault, held textual inscriptions or sculptures of rulers, deities, or zoomorphic mountains crafted in stucco, stone, or pigment (Fig. 8).

Early Maya constructions, particularly in the Late Preclassic and Early Classic, used abundant stucco decoration, for which stucco was shaped into friezes on building or platform exteriors. At multiple sites in Guatemala’s Department of the Peten, such as El Mirador, Nakbe, and Uaxactun, archaeologists have uncovered temples with monumental faces, modeled in high-relief stucco, with features denoting particular deities, such as K’inich Ajaw, the solar deity. This tradition continued in the Early Classic, most notably at Kohunlich, Mexico, and at El Zotz, Guatemala, where archaeologists discovered buildings with multiple heads of the solar deity (Skidmore, 2010) (Fig. 9).

Preclassic and Early Classic artisans also adorned temples with friezes portraying deities and ancestors in more dynamic compositions. At Calakmul, Mexico, archaeologists discovered a Late Preclassic temple whose central doorway was surrounded by a large stucco frieze, 20 m long, of the rain deity Chahk amidst supernatural birds and a cosmic crocodile (Delvendahl, 2008, pp. 29–30). At Copan, Honduras, archaeologists

uncovered a building nicknamed Rosalila whose polychrome stucco decoration transformed the building into a mountain occupied by magnificent supernatural birds that are manifestations of the ancestor Yax K’uk’ Mo’ – whose tomb lay deeper within the building – as a solar deity (Agurcia Fasquelle, 2004).

In Late Classic Copan, use of abundant stucco gave way to cut stone decoration, and subsequently artisans crafted large-scale mosaics of

local volcanic tuff into friezes of high-relief and three-dimensional sculpture (Fash, 2011). These stone mosaic friezes, like the earlier stucco ones, transformed buildings into mythological places such as Sustenance Mountain, seen on Copan Structure 22, which held stone sculptures of the young dancing Maize God, which had been set with tenons into the building façade.

Analogous to Copan’s stone mosaics are the “Chenes-style” architectural facades on buildings

Temples of the Maya,

Fig. 10 Stone mosaic frieze around doorway of Structure 2, Chicanna, Mexico (Photograph by author, © Megan E. O’Neil)

from the seventh to ninth centuries in the Mexican states of Campeche and Yucatan. Around these buildings’ doorways are mosaics comprising massive zoomorphic mouths with prominent fangs that transform the doorway into a cave opening, an entrance into the sacred, animate earth, and the building itself into a cave or mountain (Fig. 10). Notably, the stucco tradition was not lost, for at Ek Balam, Mexico, archaeologists found a magnificently preserved stucco façade of a zoomorphic face surrounding a doorway into a room enclosing a royal burial (Vargas & Castillo, 2006). This sacred mountain thus honored both earth and ancestor.

Many Maya temples venerate deceased ancestors and hold their tombs, often inside the pyramid’s base on its central axis, as at Palenque, Tikal, Piedras Negras, and elsewhere, and associated sculptures and inscriptions may commemorate that ancestor. For example, the Temple of Inscriptions of Palenque is a terraced pyramid built over the tomb of the ruler K’inich Janahb Pakal (Fig. 11). Inside the tomb, the king’s carved sarcophagus portrays him being reborn from the jaws of the underworld as a manifestation of corn, lightning, and the rising sun, while his ancestors sprout from the ground in the form of fruiting trees (Schele & Mathews, 1998, pp. 95–132; Stuart & Stuart, 2008, pp. 166–184). Lengthy inscriptions on the walls of the superstructure

atop the pyramid position Pakal within a longer ritual history of his dynasty and its patron gods. The superstructure – and the building itself – was thus a place to commemorate both the ancestor and the dynasty through acknowledgment of past rituals and continuing ritual engagements within this sanctuary.

In contrast to temples honoring particular rulers or gods, some Maya temples commemorate calendar anniversaries, such as the *k’atun*, or 20-year period. In many sites, rulers erected stone stelae (freestanding sculptures) to commemorate *k’atun* endings, and at Tikal, rulers constructed temple complexes on large platforms with twin radial pyramids, an enclosure holding a stela and an altar, and a multi-roomed building (Harrison, 1999). These temple complexes, commemorating the passage of time and the ruler’s place within it, were certainly used for performing ceremonies in both the larger plazas and the smaller sanctuaries.

The sizes of structures, associated images and texts, and material remains give clues as to how Maya temples were used. At Yaxchilan, Mexico, carved stone lintels in temple doorways show men and women performing bloodletting rites that conjure deities, indicating that bloodletting and vision rites took place inside (Fig. 12). At Palenque, the Temple of the Inscriptions texts narrate the offering of vestments to deities (Guenther, 2007), suggesting that some temples

Temples of the Maya, Fig. 12 Lintel 24, Yaxchilan, Mexico. British Museum, AOA 1886-317, AN0 (Photograph by Charles Tilford, Creative Commons, CC BY-SA 3.0)

were used to care for and dress deity effigies. At Tikal, the presence of incense burners and blackening from burning inside temple sanctuaries is evidence that the Maya made fire offerings in these buildings, likely to ancestors buried inside (Coe, 1990; O’Neil, 2009). Furthermore, inscriptions reveal that the Maya performed fire ceremonies to dedicate structures (Stuart, 1998), and material remains indicate they performed ceremonies to terminate them (Agurcia Fasquelle, 2004), as if these temples were living entities that had to be brought to life and terminated.

Maya temples were thus created and used for multiple purposes, but for contemporary Maya people, worship and ritual happen both in buildings and in places in the landscape, such as caves, mountains, or springs. We see evidence for analogous practices in the archaeological record. Many constructed temples were named as mountains or marked as cave openings and effectively embodied their natural analogs (Brady, 2001). Furthermore, archaeologists have discovered offerings and remains of fires in caves, such as Balankanche, Mexico, and the cave system of Naj Tunich, Guatemala, contains offerings and

Temples of the Maya, Fig. 13 Offerings next to “World Tree” speleothem, Balankanche, Mexico (Photography by INSIGHT, www.insightdigital.org and mayaskies.net. © Kevin Cain, INSIGHT)

painted texts and inscriptions that demonstrate that individuals traveled from multiple locations to perform rituals in the cave (Stone, 1995) (Fig. 13). This cave system was an important place for worship and ceremony; the concept of the Maya temple thus also must encompass these natural places, where Maya people engaged with gods and ancestors through ritual performance, just as they did in constructed temples.

Textiles in Africa

Gloria T. Emeagwali

Historians of African textiles now have at their disposal a wide range of oral and written documented sources. These describe significant centers of textile production over time, the raw materials, implements, and techniques used by the various cloth producers, varieties of fabric and techniques of dyeing and coloration,

symbolic expression as reflected in the finished products, and the many functions for which the latter were used. The process of technological transfer within various parts of the continent and the elaborate structure of guilds and schools of apprenticeship are also better known to us as a result of the systematic collection of oral history in some areas.

From the Northeast African Nile region to West Africa and elsewhere, travel reports, missionary reports, and even autobiographies have provided details about aspects of the development of cloth making techniques. Herodotus in his travels in Egypt as far as the first cataract obtained specific knowledge about the implements used by the Egyptians and the existing division of labor. Such information has complemented the archaeological evidence brought forward by teams of Egyptologists as they continue to come in contact with numerous reams of cloth in the mummified corpses and burial goods which the Egyptian nobility, like some of their counterparts in West Africa, sent along with the dead to the afterlife.

In the case of Ethiopia, travel reports by missionaries, explorers, and travelers such as Francisco Alvarez, Jerome Lobo, Charles Poncet, James Bruce and Henry Salt, provide direct and indirect information on the variety of textiles in the Axumite and post Axumite realm. For West Africa in the eighteenth and nineteenth centuries, Mungo Park, Barth, and Baikie complement the perspectives diffused in the missionary reports of Trotter, Allen, and Crowther, who emphasized that the people of Onitsha, Eastern Nigeria, like their counterparts elsewhere, "manufacture their own clothes generally plain or fanciful with cotton grown in their farms" (Crowther, 1968).

Archaeological reports have been no less useful than the eyewitness travel and missionary accounts cited. Reams of linen and cotton have been found in Egyptian tombs, and the Sudan, also one of the Nile Valley kingdoms, has yielded cloth and looms dating back to 500 BCE. The Igbo-Ukwu finds of Eastern Nigeria included thousands of artifacts, among which was cloth dated to the ninth century. The Bandiagara cliffs

of Mali have yielded textile products dated to the eleventh century. The evidence from the excavated pits complements the various collective recollections reflected in poetry, song, and narrative accounts no less than the honorific codes and titles and range of linguistic terms accorded textile specialists and their products. Some city states and towns in the African continent gave their names to a product line, as was the case of Akwete and Okenne in Eastern and Central Nigeria, West Africa.

Whether in renowned Nigerian textile centers such as Kano, Iseyin, Bida or Akwete and Okenne, or in the Wolof empire of Senegal, the Bambara kingdoms of Mali, the Mossi Empire of Burkina Faso, or the Baule polities of the Ivory Coast, we can identify some basic raw materials, production instruments and techniques, as well as common tendencies relevant to textile not only in West Africa, where the latter regions were located, but also in Central, East, and Southern Africa. Raw materials were derived from vegetable or animal products and generally involved wool, camel hair, flax, cotton, the leaves of the raffia palm (*Raphia rufia* or *Raphia vinifera*), silk from cocoons, and bark from the baobab tree. In all the above cases, with the exception of bark, which was hammered into shape, there developed over time sophisticated spinning, weaving, and dyeing techniques which included the gradual invention and improvement over time of vertical and horizontal frames, lower and upper beams, beaters, shed sticks, hecklers, shuttles, and templars, all various components of the horizontal and vertical looms produced across the continent.

African textiles, by the nineteenth century, included a wide range of fabrics, each influenced by the base material from which the thread was made, the texture of the thread, the width of the strip woven cloth, the alignment of the thread, and the intensity of inlays and the dyeing procedure, whether starch resist or not. Indigo, guinea corn stalk, the bark of the locust tree, the leaves of the tombolo tree, combined with ash potash and any of a long list of colorants were used to produce blue, red, buff, rust, or brown and other colors. Dyes were derived from experimentation

with vegetable and other products. The famous *Kente* cloth of strip woven silk (sometimes interlaced with threads of gold and very often confined to the Ashanti nobility), *Sanyan*, Western Nigeria's silk derived fabric, *Adrinkra*, the hand-printed cloth of the Ivory Coast, and *Sotiba* of Senegal, are some of the various types of textile products which have become household names in the continent.

A wide range of symbols was reflected in cloth through the representation of motifs of special shapes, figures, dimensions, and sizes. These were either impressionistically done by the use of geometrical shapes and symbols or were made to reflect naturalistic images derived from African cosmologies and indigenous belief systems. It was common for Dahomean quilts to portray images of the founding fathers of particular dynasties. A lion represented King Gelele and a buffalo King Gezo, whilst a representation of a ship was the symbol of King Agaza – all historic figures in the making of the Dahomean (Beninois) state. More recently, worldly events ranging from the American soap opera *Dallas* to statements about the prevailing economic reform programs have been coded into fabric. A study of African textile over the centuries yields information not only about changes in technical expertise and accretional gains made from the intraregional and interregional exchange of ideas, but also the prevailing lifestyles, philosophies, and world views of Africans in various parts of the continent. Textiles in themselves provide a rich source of historical information. They were associated with many activities and had many uses. They were a medium of exchange in barter, or units of currency in a wide range of commercial transactions. Tax payment was collected in the form of textiles and so too tribute. Since fabric differed in cost and the degree of technical expertise associated with various types, it was easy for it to become a symbol of wealth, extravagance, and conspicuous consumption. Cloth very often was a symbol of class affiliation. Saddle cloth and the overall accoutrements of the horse included specialized fabric, as did the panoply associated with Ashanti royalty. Cloth had special burial functions. Specialized fabric was associated

with shrines of the dead. Marital gifts, whether prenuptial or not, tended to include cloth as part of the expected dowry. Decorative and symbolic objectives were matched by functional and practical ones. Cloth was used for protective purposes against the elements, as sheets and covers, and also to make rice bags, purses, or tents.

The reproduction of knowledge systems was done through institutionalized apprentice systems of guilds, each of which adhered to strict codes of conduct and behavior. Fees in cash or kind were paid by the apprentice who was expected to “gain freedom” after periods agreed to in the context of elaborate ceremonies. These guilds themselves had a hierarchy of officials who in many cases were of significant political clout. The teaching and training of spinners, weavers, and dyers was therefore organized in the context of established custom and practice, even though there was a general tendency for specialization to be restricted to specific lineages within various regions.

There is evidence that Africans imported cloth in the context of the trans-Saharan trade as well as the trans-Atlantic, but these importations were complementary to a wide range of indigenous textile products. It was not unusual for various political elites to flaunt some of the imported textiles along with indigenous products, or for textile specialists to unravel an epic of imported fabric with the objective of isolating particular reams of thread. The British industrial revolution had specific implications for African textiles, given the fact that factory produced cloth was cheaper with the mechanization of spinning and weaving. The successful transfer of textile technology from India to Britain by the nineteenth century meant that the British factory system was able to churn out some relatively attractive textile products for the African consumer. This, however, did not lead to the destruction of the indigenous textile sector which continued to be a dominant component of the informal sector well into the twentieth century, despite some ill-intentioned legislation and policies during the period of colonial rule.

Contemporary Africa is home to a wide variety of indigenous textiles. Local factory-

produced cloth has had to compete with Taiwanese, Indonesian, and Dutch imports, most of which are imitations of indigenous African fabric. IMF and World Bank conditionalities tend to call for the removal of duties on imports and therefore undermine those local textile centers, some of which lack the productive capability to compete on the open market. In spite of these trends, however, there is every indication that African textile producers will continue to have a large share in the market and continue to experiment, innovate and produce the high quality textiles historically associated with the continent.

Textiles in China

Dieter Kuhn

A textile is here understood as a woven fabric made from a wide range of raw materials. Some of these were silk, cotton, wool, and the bast fibers ramie (*Boehmeria nivea* L.), hemp (*Cannabis sativa* L.), and the bean- or vine-creeper (*Pueraria thunbergiana*), which possessed the greatest economic and cultural importance in pre-Mongol (prior to AD 1279) China. The development of textiles is described

here on the basis of archaeological evidence and from the view of its cultural importance.

The origin of weaving can be traced back to basketry and matting techniques from the Neolithic. Impressions on ceramic sherds and fragments from the archaeological sites of Banpocun near Xi'an in Shaanxi and from Hemudu in Yuyao county in Zhejiang prove that they existed in China as early as the fifth millennium BCE. The earliest finds of textiles are from southeast China. There is a complicated fragment of fabric, made of *Pueraria thunbergiana*, found at Caoxieshan in Jiangsu province and dated to the fourth millennium BCE. Its structure features a combination of hand twining and loom weaving techniques. A number of silk belts, a piece of silk, and a scrap of ramie cloth were discovered in a ► [bamboo](#) box excavated from the site of Qianshanyang in Wuxing in northern Zhejiang, dated to ca. 2750 BCE.

Small stone-cut and jade figures were found in various Anyang sites from the Shang period (sixteenth–eleventh centuries BCE). They clearly show “textile ornaments” which give an impression of Shang clothing and fashion. Apart from furs and leather, especially suitable as winter clothing and used for ceremonial occasions, hemp and silk were tailored. Tailoring does not mean cutting pieces of fabric so as to make them fit but simply sewing pieces of fabric together, only allowing a few corrections. It was probably the Shang people who introduced right side fastening and a hair-dressing style which could be distinguished from the barbarians. Most garments including lined garments were buttoned on the right side under the right arm. Very often the overlap of a robe was unbuttoned. *Obi*-like waist-belts kept the coat and the undergarments in position. Women's dress included a skirt. Women had their hair styled in a cylindrical shape, and flat rather high round caps were common. Upperclass people wore gaiters and shoes that curled upwards to the toe. Geometrically patterned fabrics (*T*-, *hui* and *lozenge*-patterns) were exclusively used as borders of garments, at the openings of the sleeves, at the collar, and along the overlap, for girdles and waist-belts,

caps and hats. Colorful painted and embroidered silk was available to the higher echelons of Shang society. Certain important weaving techniques were applied to produce silk fabrics as early as Shang times:

1. Tabby weaves with threads of almost identical diameter and a thread-count of warp and weft between 8:7 and 75:50 cm⁻¹;
2. Warp-faced tabby, also called rep or rib, where the number of warp-threads is roughly double the number of weft-threads per centimeter;
3. Monochrome tabby patterned with twill (3/1), very often named twill damask (*wenqi*). The ground weave is a tabby weave, and the pattern is woven in twill weave with the warp-threads forming the pattern;
4. Tabby crêpe (*zhou* or *hu*) with a thread-count of ca. 30:30 cm⁻¹. The warp-threads show a twist with 2,500–3,000 twists per meter. The weft-threads are twisted together from several threads in an *S*-twist showing 2,100–2,500 twists per meter. The strong twisting of the threads causes the crêpe effect;
5. Crossed-warp weave technology was known and used.

The most important and spectacular textiles of the Zhou period (1045–221 BCE) discovered so far are from central and southern China, especially from Jingzhou in Hubei and from the region of Changsha in Hunan. In Western Zhou times (1045–771 BCE) the *jin* brocade appeared, an outstanding weave which on the one hand was produced on a rather complicated loom and on the other hand asked for expert craftsmanship. This so-called brocade was a new type of warp-faced compound weave with the warp divided into at least two series, normally of different colors. Even picks of weft interlace with the warp either in tabby or twill. Although this weaving method produced polychrome silk fabrics with a colorful shiny and mostly geometric pattern on the surface, its repertoire was still limited by the weaving technology at the time. Weavers exhausted the technical possibilities of their looms and composed scenes and figures

which were evidently intended to be pictorial descriptions, but they are still symmetric with straight lines and cornered outlines. Embroidery helped to make the patterns of tigers, phoenix, dragons, birds, and blossoms appear more lively. The patterns were arranged in various ways adorning the silk robes of the fourth and third centuries BCE.

In 1972 outstanding textile fabrics and garments totalling more than 100 objects were unearthed at tomb no. 1 at Mawangdui in Changsha. The tomb belonged most probably to the Lady Dai (d. 168 BCE). Among the well preserved fabrics and garments there were more than a dozen robes of various make, such as 11 floss-wadded robes, 1 lined robe, 3 unlined robes, several blouses and skirts, 2 pairs of socks, 4 pairs of shoes, 3 pairs of gloves, pillow covers, 46 rolls of single-width silk fabrics, and many more items of daily life. The textiles exhibit an unrivaled excellence in weaving skills, the mastering of pattern design, and imagination in applying all sorts of patterning techniques. Favorite weaves were thin and loosely structured gauzes (*sha*) and lozenge-patterned leno (*luo*), a fabric of open structure which is made by cross-warp yarns.

The most sophisticated weaving techniques and looms were used to produce brocade with small geometric patterns. A new technical dimension of weaving becomes obvious with the pile-loop brocade, a velvet-like fabric with geometric patterns of different sizes. Forty silk garments are embroidered with the colorful and curvilinear designs of *xin qi* (abiding faith), *changshou* (longevity), *cheng yun* (riding on the clouds), and various plants and cloud patterns. Embroidery as a patterning technique lost some of its importance when by Eastern Han times (AD 25–220) the variety of weaving patterns was finally extended to include mythological beasts, birds, fishes, flowers, all sorts of four-legged creatures, and Chinese characters.

The brocade manufactured from Han to early Tang times (seventh century) was woven with warp-faced patterns. The colors of the previously dyed warp threads mounted on the looms dominated the patterns. The patterns could be as wide

as the width of the fabric (ca. 50 cm) but their length was rather limited. Probably during the eighth century of the Tang dynasty a dramatic innovation took place. The weft-faced patterning method as it had already been practiced in a few woollen textiles from Han times was now widely applied to silk weaving. The advantage of weft-patterning was that the colors of the pattern produced by the weft could easily be changed, which resulted in larger and more vivid pattern units. Furthermore the dressing of the loom was facilitated. After the Tang dynasty, the weft-faced patterning method gained predominance in brocades and in other weaves. At the same time the cultural influence of Central Asia became evident in textile patterns. Apart from several hundred fragments of silks unearthed in 1987 from the underground palace of Famen Temple near Xi'an, most textile finds from the Tang period were discovered in the dry desert region of Turfan (Xinjiang province) and in the cave temples of Dunhuang.

If satin weave (*duanwen*) is classified as an irregular twill (*xiewen*), then satin could have been created as early as Tang times. Whereas the interlacing points of warp and weft in twill weaves are arranged in a continuous oblique line, those points in satin do not form a line but are evenly distributed, thus allowing long floats of the threads which give the fabric a glittering and at the same time smooth appearance. The French name *satin* was derived from the word *zaituni* which was used by Persian merchants to name the city of Citong at the coast of Fujian, another name for the famous commercial center of Quanzhou in the Song period (AD 960–1279). Several well preserved complete sets of official robes, garments of various types, underwear, and other textile items were found in three Song tombs. The tomb of Huang Sheng (1226–1243) in Fuzhou in Fujian province, who was the daughter of an official and married to an imperial clansman, contained 354 textile items, of which 201 were articles of clothing. The textiles are of top quality. The weavers and textile printers made use of the most advanced techniques of their time in producing figured leno (*hualuo*), gauze (*sha*), crêpe (*zhou*), and figured twill silks (*ling*). Even a few

satin weaves (*duan*) are described. More than 30 textile items were discovered in the tomb of the student of the Imperial College Zhou Yu (1222–1261) in Jiangsu province, and the recently excavated tomb of Mme. Zhou (1240–1274) in Jiangxi province yielded 329 items of textiles. Among the many regional brocades produced, the pure red brocade from Sichuan (*Shu jin*), with a formidable array of realistically depicted designs, was most famous.

In northern China, where the Liao dynasty reigned from AD 916 until 1125, and in the Song empire, the use of various types of tapestry (*kesi*) became highly fashionable. Among the textiles recovered from the Liao tomb of Yemaotai, dated between 959 and 986, there was a shroud made of silk tapestry in gold threads with a powerful design of dragons. The forerunners of this *kesi* tapestry technique can be traced back to the *zhicheng* technique of Han times, an intricate inlaid pattern produced by the weft yarn employing the swivel weaving method. During the Yuan and the Ming dynasties the use of various types of weaves with gold threads (*jinjin*) increased. The weavers of Ming times, especially the craftsmen of the cloud pattern brocade (*yunjin*) from ► [Nanjing](#) mastered a swivel weaving method (*zhuanghua*) making use of colored wefts to form a pattern on a fabric of various weaves. In many cases a glossy satin served as ground for the colorful swivel weave.

Three types of pile fabrics were produced on a large scale in Ming and Qing dynasties. The *Zhang* satin, originally from Zhangzhou in Fujian, was a figured warp pile fabric. From early Qing times until the end of the eighteenth century its main centers of production were Nanjing and Suzhou. The *Zhang rong* was a velvet where in order to produce a pattern the loops in the pattern area were cut. Thus the velvet pattern stood out on a ground of loops. The *Jian rong* was a cut pile fabric made of black silk threads produced on looms in Nanjing.

For the dragon robes (*longpao*) of the imperial Ming and Qing courts, the formal Manchu court robes (*chaofu*), and the semiformal coats (*qifu*) all patterning techniques known at the time were employed. This applies especially to the robes

manufactured during the reign of the Qianlong emperor after 1759. Many of the old weaving techniques were handed down from generation to generation and can still be found in China.

Textiles in Egypt

Gregg De Young

The American University in Cairo, Cairo, Egypt

Egyptian textiles during the Dynastic Era (3100 BCE–300 BCE) were primarily linen, although wool was not unknown. (Cotton and silk were introduced only later.) Linen was produced in three basic grades: royal or fine linen, thin cloth, and smooth cloth. Production of royal linen, the highest grade, was a palace monopoly. Its manufacture took place both in the royal palace and in workshops associated with state temples. These workshops were supervised from the royal harem and were obligated to provide specific amounts of linen annually for use in the royal household and in temple rituals. Presumably it was this highest grade of linen that was also used in international trade.

As is often the case, much of our knowledge of the processes for textile production, use, and care is derived from scenes portrayed in the funerary art of the social elite and tomb models showing textile workshops, coupled with the study of surviving textile examples (and Egypt's dry climate has helped to preserve many pieces of textile). These evidences reveal a remarkably sophisticated industry for the production of cloth and clothing. Modern archaeology increasingly realizes the importance of textile evidence in dating artifacts, as well as in offering invaluable evidence concerning the daily life of all classes of ancient Egypt society.

The typical color of Egyptian linen ranged from near white (when made from young, immature, flax plants) to golden brown (from fully mature flax). The Egyptians did not ordinarily color their linen because most of the dyes known to them were not colorfast. When one desired to dye either a finished piece of linen cloth or linen thread to be used in embroidery, it was necessary to treat the fabric first with a mordant (one of the several substances, such as alum, that would adhere to the fibers of the linen and facilitate chemical

bonding with the dyestuff) and then with the dye itself.

Tomb paintings show Egyptians harvesting flax by pulling it up by the roots, rather than cutting the stalks so as to produce the longest fibers possible. Since basic techniques of flax processing are never illustrated in scenes from ancient Egypt, we do not know the details of the Egyptian processes. The following steps would need to be done, however. After being dried, the stalks were drawn through a comblike device to remove the seeds (ripping). The stalks were then exposed to moisture and allowed to rot slowly (retting) so that bacteria could break down the pectin in the tough outer sheath. After drying, the stalks were beaten (breaking) and sometimes scraped (skutching) in order to separate the woody parts from the long, flexible fibers that would form the linen. A final combing (hackling) cleaned and prepared the fibers to be spun into thread.

In preparation for spinning, the flax fibers were rolled together, usually between the palm and the left thigh, forming a loosely twisted strand. These strands were wound into loose balls on a pottery reel and stored in clay or basketry containers until ready for spinning. Based on artistic representations, the Egyptians used three different techniques to rotate the spindles while twisting the thread together. The supported spindle was rotated by being rolled between the palm and the leg of the spinner (usually from knee to thigh). The grasped spindle was rotated between the palms. The suspended spindle was set spinning (again by rolling from knee to thigh) and allowed to drop and swing freely, its rotary motion being maintained by the weight of the whorl, the drum-shaped or dome-shaped stone, or ceramic attachment near the top of the spindle shaft, which acted as a kind of miniature flywheel. The dropped spindle produced the most constant tension on the thread, permitting a finer and more homogeneous thread to be produced.

The earliest looms were simple ground looms in which two parallel beams supporting the warp threads were placed on the ground and held firmly in place with pegs. At about the beginning of the New Kingdom (ca. 1550–1085 BCE), we also

begin to find portrayals of a vertical-framed loom in which the two beams were incorporated into a less portable rectangular wooden frame. Some have speculated that this innovation may have been introduced when Egypt was dominated by the “Sea People” or Hyksos (ca. 1700–1550 BCE).

When thread was ready for weaving, the warp threads were attached parallel to one another between the two main beams of the loom. In the simplest weaving, the weft thread was passed over and under alternate warp threads. On its return, the path of the weft thread was reversed, so that it passed on the opposite side of each warp thread. A stick or comb was often used to beat down and press the weft threads together. There are, of course, many variations on this basic tabby weave, some of them of considerable complexity. Various weaving patterns were used to provide some visual interest or decoration to the fabric.

Based on artistic evidence, it appears that men were most frequently involved in the cultivation and harvesting of flax and in the preparation of the fibers for spinning. Both men and women (and even children) are shown involved in the spinning of the fibers into linen threads. Women, however, seem to be the ones who work at ground looms, while men more often are shown working at vertical looms. Whether these representations reflect a true division of labor or only an artistic convention is unclear.

Woven cloth was cut either with a metal shears or a knife when the ancient Egyptian wished to fashion a piece of clothing. The pieces were sewn together using a linen thread and a needle of polished wood, bone, or metal (usually copper or bronze, but occasionally gold or silver). The pieces were held together during sewing with pins of the same composition. Both needles and pins tended to have larger dimensions than modern examples. Pins were frequently capped with a looped head, which may have served a decorative purpose. Seams and hems were frequently rolled and secured by a rather crude whipping stitch. Seams that might experience greater stress or wear might be joined instead with flat seams. There were, as today, many

experiments with decorative sewing in order to produce an aesthetic effect.

Considerable effort was often expended to repair damaged garments. Usually repairs were in the form of darning (reweaving), rather than patching. The more ordinary grades of linen, however, were repaired with considerably less effort. A frayed edge might be bound carefully with a whipping stitch, but more serious damage often led to the object being discarded and replaced. Sometimes outworn garments were torn into strips to use in wrapping mummies.

From as early as the Old Kingdom (ca. 3000–2700 BCE), there are indications that laundering was done for wealthy households and temples. Washermen often formed a kind of guild. In the New Kingdom, the Superintendent of the Washermen seems to have enjoyed nearly as much prestige as the sandal bearer within elite households. (In most households, the laundering would have fallen to women or slaves.) Clothing was collected from subscribing households, identified using specific markings and listed on *ostraca* (pottery shards or flakes of limestone), and taken to the riverside laundry. There it would be treated with natron or other types of surfactants, beaten with sticks or stones, rinsed, wrung out, and spread to dry and bleach in the hot Egyptian sun. When fully dry, it would be folded, bundled, and returned to its owners.

Textiles in India

Vijaya Ramaswamy

India may be described as one of the ancient centers of the cotton textile industry, since early evidence of cloth has been found in prehistoric archaeological sites. The spinning and weaving of cloth was very much a part of everyday life in ancient India. The loom is used as poetic imagery in several ancient texts. The *Atharvaveda* says that day and night spread light and darkness over the earth as the weavers throw a shuttle over the loom. The Hindu God Vishnu is called *tantuvardhan* or “weaver” because he is said to have woven the rays of the sun into a garment for himself.

It is interesting to note that in the third or second century B.C.E., when the cotton industry in India was in a flourishing state, in Europe cotton was still virtually unknown. The Greek scholar Herodotus thought that cotton was a kind of animal hair like sheep’s hair. At the beginning of the Christian era, Indian textiles figure prominently in the trade with Rome. Arrian, the Roman historian, testifies to the export of dyed cloth from Masulia (Masulipatnam on the Coromandel coast), Poduca (Pondicherry), Argaru (Uraiyūr in Tanjavūr district, Tamil Nāḍu) and other places in south India. Legend has it that Indian cloth was purchased in Rome for its weight in gold. The quality of Indian dyeing too was proverbial in the ancient world, and in St Jerome’s bible, Job says that wisdom is more enduring than the dyed colors of India. Indian textiles even passed into

Roman vocabulary as is seen by the use as early as 200 B.C.E. of a Latin word for cotton, *Carbasina*, derived from the Sanskrit *kārpasa*.

The history of Indian textiles constitutes one of the most fascinating and at the same time tragic chapters in Indian history. In the sixteenth century the Portuguese first set foot on Indian shores and were followed in quick succession by the Dutch, English, and French. For the next hundred years “Indian cotton was king” and Europe was in the grip of what economic historians describe as “the calico craze.” Indian textiles were used in the Middle East, Africa, and Europe not merely as dress material but also as coverlets, bed spreads, and wall hangings. The joint English sovereigns William and Mary are described as having landed in England in 1689, resplendent in Indian calico. Daniel Defoe, the author of *Robinson Crusoe*, commented that Indian calico, which at one time was thought fit to be used only as doormats, was now being used to adorn royalty.

However, there was a dramatic reversal of fortune in the eighteenth century. The cotton revolution in England rendered redundant the products of Indian handlooms. The first ban on Indian textiles was imposed by the British crown in 1700 and repeatedly after that. By the end of the century, instead of Indian cloth being exported abroad, the Indian market was flooded by the machine-made cloth of Manchester and Lancashire. Around the same period, India was hit by one of the worst famines beginning in the late seventeenth century and continuing through the eighteenth century. The words attributed to Lord Bentinck, the Governor of India in the 1830s, that “the bones of the weavers are bleaching the plains of India” are a dramatic but apt description of the fate of the Indian weavers.

The eclipse suffered by the Indian textile industry lasted until the early twentieth century until its grand revival under Gandhi, who initiated the *khādi* movement. The *charkhā*, or Indian spinning wheel, and *khādi*, or homespun cloth, became symbolic of the Indian struggle for independence. Foreign cloth was burnt in the public squares and the Indian spinning wheel became a part of the home of every Indian patriot.

Since Independence, a sea change has occurred in the traditional Indian textile industry. The changeover to power looms and jet looms and the introduction of computer designs is setting new traditions in Indian textiles. In the course of its historical vicissitudes, the Indian textile industry has gone through a process of change as well as cultural assimilation.

Indian Textile Technology

The first process in the weaving of a cloth is warping and sizing, and in India this is done in the open. ► **Bamboo** sticks, about 120 in number, are fixed upright in the street or what is called the warping grove, at a distance of a cubit from one another. Rows of women walk up and down the line, each carrying a wooden spindle in the left hand and a bamboo wand in the right. As they walk, they intertwine the threads between the split bamboos. These threads are then stretched horizontally from tree to tree, evenly washed with rice starch and carefully brushed. The right amount of tension in the warp is required to prevent the yarn from breaking while on the loom.

In India spinning was and still is almost exclusively the occupation of women. More specifically, this was the sole occupation of destitute women and widows. It is interesting that this corresponds to the English notion of the “spinster” as one who has to spin for her livelihood since she has no one to support her.

The earliest looms in use in India were either the pit loom or the vertical loom. The *Atharvaveda*, probably compiled in the early pre-Christian era, says, “A man weaves it, ties it up; a man hath borne it upon the firmament. These pegs propped up the sky; the chants, they made shuttles for weaving... (sic).” However, the most common type of loom in use was the horizontal pit loom in which the loom is placed inside an earthen pit and is operated with foot treadles. By depressing the pedal with one foot and raising the other, one set of threads get depressed and the weaving shed is formed through which the throw shuttle is shot across

by hand. References to such looms are scattered throughout ancient and medieval inscriptions. Around the fifteenth century one begins to get reference to the draw loom. This would consist of several levers and so enable the weaving of complex patterns. The introduction of the fly shuttle in the 1930s toward the end of British rule in India resulted in the partial mechanization of loom technology and in another three decades this was followed by the introduction of the jacquard. Nowadays, partially mechanized looms, power looms, and jet looms are displacing the traditional Indian handloom.

Traditional Indian Costumes

Different types of cloth are worn and woven in the different parts of India, since this is a vast land with varying climates. Generally, men tend to wear a longish lower cloth of about one and a half yards in length, called *dhōti* or *lungi* in the north and *veshti* in south India, while the traditional upper cloth consists of a single piece of cloth called *aṅgavastra*. However, in hot weather, men generally go without the upper cloth. In many parts of northern India, men also wear a head gear against the dust and heat. This is especially true of desert regions like Rajasthan. The Indian women wear large skirts or loose trousers called *salwār* and longish or short jackets. Alternately, they wear a 6-yard piece called a *sāri* and a blouse for the upper part. In the colder parts of India, such as the Himalayan mountain ranges and Kashmir, the garments are thicker and more elaborate, including warm woolen shawls and heavy jackets. It is noteworthy that in antiquity, stitched garments such as shirts, trousers, and blouses were hardly ever worn in India. In the ancient sculptures and paintings such as the ones at Amarāvati or Brahādīśvaram, it is only the menials, palace attendants, common soldiers, and dancing girls, all of them belonging to the lower echelons of society, who are depicted wearing stitched garments. Such garments are never depicted on the upper classes or royalty nor on the images of gods and goddesses. A plausible reason may be the

association of impurity and pollution with stitched cloth.

Colors and Designs in Textiles

Traditional Indian textiles reflect the Indian ethos. There is an aura of religion and romance around Indian weaving. Everything is significant – the colors chosen, the motifs, and the wearing occasion. Crimson or shades of red are very auspicious and worn by women on the occasion of their marriage as well as by ceremonial priests in certain parts of India, such as the Madhvā Brāhmins of Karnāṭaka. White represents purity and ochre, renunciation, and these are the colors worn by Hindu widows as well as ascetics. Yellow and green denote fertility and prosperity and are worn in the spring. Black is considered inauspicious, although pregnant women in south India wear black, perhaps to ward off the evil eye. As late as the eighteenth century, coloring was done entirely through vegetable dyes such as madder and indigo, although now dyers have almost entirely switched over to chemical dyes except in the case of highly specialized textiles like the *kalamkāris*.

The earliest designs on Indian textiles seem to have been geometrical. A twelfth century Sanskrit text called the *Mānasollāsa* described textiles designed with dots, circles, squares, and triangles. The depiction of flora and fauna was related to religion and popular beliefs. The lotus, which has great spiritual significance in Hinduism, and the mango design are among the most popular Indian motifs. Swan, peacock, parrot, and elephant are also commonly depicted. The tree of life, which symbolizes fertility and prosperity, is another auspicious motif. All these designs are patterned on the loom itself and it may take a handloom weaver working on an ordinary frame loom as long as 30 days to weave an elaborate 6-yard *sāri* with designs and gold lace. As the weaver weaves, he also sings the special loom songs, a tradition which has now almost entirely died out except perhaps in some interior weaving villages in Uttar Pradesh or the remote south. These loom songs

tell of the glory of particular weaving castes or they are full of esoteric religious metaphors describing god as the eternal weaver, weaving the web of life, and the human body as the cloth he has woven.

Textile Varieties

Traditional Indian textiles are unique and unparalleled for their beauty. The *jāmdāni* is an elaborate textile which is woven with multiple shuttles and resembles tapestry work. Floral motifs called *bootis* in gold or silver lace are scattered over the body with heavy gold lace on the borders. The most striking of these designs is the *pannā hazāra*, literally a thousand emeralds, in which the flowers shimmer and gleam all over the sari. The Benarsi *sāris* called *Kimkhābs* woven in Uttar Pradesh are legendary for their loveliness, although Benaras in the north and Kānchipuram in the south were traditionally associated with pure cotton rather than silk. It was the British who introduced sericulture in Kanchipuram in the nineteenth century. Gadhwāl and Venkaṭagiri saris of Andhra and the Īrkāl saris of Karnataka specialize in rich gold borders and heavy panel-like *pallūs* (that portion of the *sāri* which is draped over the shoulder). Another variety is the tie and dye (called variously *bandini*, *ikāt*, or *chungdi*) produced in Rajasthan, Orissa, Andhra Pradesh, and Madurai where the fiber is tie-dyed before weaving. A unique Andhra textile is the *telia*, which was soaked in oil before weaving and catered exclusively to the West Asian market because it was woven to suit desert conditions. This textile appeared in the sixteenth century with Muslim rule and died out with the collapse of the Islamic empires. Another textile which became popular in the mughal period was the *mashroo* (also the *himroo*) in which cotton was used in the warp and silk in the weft. Initially these were used as Islamic prayer mats by the Mughal nobility who were forbidden by Islamic tenets to use any animal product. They therefore contrived the mashroo which enabled them to have their comfort without violating the religious tenet against the use of pure silk.

Textiles also form an important part of temple ceremonials such as the flag cloth hoisted in temples, the garments put on the deity, the cloth covering the chariots in which the deities are taken out on a procession and the ritual dance costumes. The *kalamkāri* cloth of Andhra, in which mythological stories are sketched minutely on cloth with a fine pen as well as the *Nādhadwāra pichwāis* of Rajasthan, are of this genre. In India it is also the practice among wandering groups of minstrels to render dramatic narrations of mythological stories, and the elaborately painted screens used on these occasions form an important aspect of traditional Indian textiles.

Textiles in Mesoamerica

Carolyn Jones and Tom Jones

Because textiles are rare among the artifacts of cultures known to us only archaeologically, any analysis of them, or of the technology of their production, must be pieced together from indirect sources. In Mesoamerica, while archeological finds attest to the existence of various textile technologies at specific dates, much of our understanding of the subject comes from ancient Maya,

Mixtec, and Aztec books, stone sculpture, painted pottery, murals, clay figurines, European documents from the time of the Conquest, and modern textile traditions.

Though the physical environment of Mesoamerica generally precludes the survival of perishable artifacts, textiles have none the less survived from certain areas. The majority, mostly small fragments, have been found in dry caves in the arid regions of Mexico. In the humid southern lowlands very little has survived, some 2,500 carbonized fragments dredged from protecting mud at the bottom of the Sacred Well at Chichen Itza are the most important single find.

The oldest textiles to survive in Mesoamerica are cordage, netting, and basketry, worked in vegetal fibers other than cotton, with early examples dating to at least 7000 BCE in Oaxaca and to 5000 BCE in central and northern Mexico. Such textiles are fashioned from the leaves and stems of various plants worked without the benefit of a loom. In instances where fibers were extracted from their plant sources, they were probably spun by rolling them together between the hand and thigh, as no tools for spinning have been found. Spindle whorls and evidence of loom woven textiles appear much later.

The earliest evidence for loom weaving in Mesoamerica consists of fabric-impressed ceramics datable to 1500 BCE, at which time spindle whorls also begin to appear. Woven cotton fragments follow soon after. These early woven textiles are worked in plain weave and almost certainly were created on a backstrap loom. From these simple beginnings, a sophisticated textile industry developed.

The weaving process begins with the selection and preparation of suitable materials. The predominant fiber of woven Mesoamerican textiles was cotton, *Gossypium* spp., with both annual and perennial varieties reported at the time of the Conquest. Cotton was cultivated in at least two colors, white and brown, and traded throughout ancient Mesoamerica. Other fibers, generically termed istle (from the Nahuatl *ixtli*), were drawn from the leaves and stems of many plants of more local distribution, including *Agave* spp. and *Apocynum* spp. Both cotton and istle required

much preparation prior to spinning and weaving. Cotton was carefully picked over, its numerous small seeds and other vegetal debris removed by hand and the mass of fiber then fluffed or beaten to produce a uniform, smooth mass. Istle, on the other hand, was toasted, split, and scraped to remove the plant flesh from fibers which were then washed, dried, and combed. No animal fibers are known to have been used in ancient Mesoamerica. Textile headdresses incorporating human hair, however, have been found.

Both cotton and istle were spun on the spindle, a simple device consisting of a “whorl” wedged onto the end of a straight-tapered shaft. A mass of fiber was attached to the shaft, which was then twirled, imparting twist. The whorl helped the device to spin easily and for an extended time, and provided weight against which the fiber could be drawn out and twisted into thread. Different fibers required different types of spindles and sizes of whorls. Cotton, because of its very short fibers, was spun on a small spindle, the lower end of which was supported in a bowl or on the ground. The longer istle fibers required a larger, heavier spindle. Yarns of any size could be created and some as fine as 0.005 mm in diameter have been recovered. Yarns could be used singly, or two or more individually spun strands could be retwisted (“plied”) together. A mixture of cornmeal and water was likely applied to some yarn to smooth and strengthen it for weaving.

While there is little archeological evidence for the use of dyes, Post-Classic pictorial codices and reports of the *conquistadores* both attest to the vivid colors of Mesoamerican textiles. Plant dyes probably included indigo (*Indigofera anil*) for blue, brazilwood (*Caesalpinia* spp.) for red, logwood (*Haematoxylon campechianum*) for black or blue, annatto (*Bixa orellana*) for orange, and many other leaves, seeds, roots, barks, and fruits. Two animal dyes were important: on the Pacific coast, purple was extracted from small mollusks of the genera *Thais*, *Murex*, and especially *Purpura*, while in arid regions, cochineal (*Coccus cacti*, a scale insect of the order Hemiptera) was cultivated on the prickly pear cacti (*Opuntia* spp.). The beautiful red produced by cochineal

was much admired by the Spanish, and the dye-stuff became a major export to Europe following the Conquest. Mineral pigments, such as ochre, iron pyrite, cinnabar, carbon, copper sulfate, and “Maya blue” clay were known, and there is some evidence for the use of mordants which make dyes more permanent. Dyes and pigments were applied by painting, by stamping or rolling with figured clay implements, and by immersion dyeing. Patterns were produced during dyeing through the application of resists and through tying-off of sections to create undyed areas of yarn or fabric. Fabric incorporating tie-dyed warp, called *jaspe*, is still produced in Guatemala today.

Once suitable yarns were spun and dyed, the process of setting up the loom began. The *Florentine Codex*, a documentary of Aztec life and custom written by the Spanish friar Sahagún just after the Conquest, illustrates the weaver’s equipment, including spindle, warpboard, loom sticks, backstrap, and batten. It also describes the training of weavers, from the presentation of the newborn girl with miniature weaving equipment, to the day of a woman’s death when her loom and spindle were burned in the funeral pyre awaiting her in the afterworld. In the *Mendoza Codex*, created by Aztec scribes at the order of the first Viceroy of New Spain, there is a section devoted to a mother’s training of her daughter in domestic chores. It portrays the child’s instruction in spinning (Fig. 1) and weaving, from ages 3 to 14, her food rations, and punishments for unacceptable work.

Information about weaving is also contained in Maya books, whose almanacs provide endlessly repeating prognostications for the timing of certain quotidian activities. One almanac in the *Madrid Codex* depicts the process of preparing the warp for the loom (Fig. 2). The weaving goddess, named *Sak Na* in the accompanying hieroglyphic text, is shown seated cross-legged with her left hand against a horizontal frame supported by at least two vertical posts and with lines stretched between their projecting upper parts. Her raised right hand holds an inverted spindle from which thread reaches to the frame before her. While there have been varying

Textiles in Mesoamerica, Fig. 1 An Aztec woman instructs her 7-year-old daughter in the art of spinning cotton on a supported spindle. The child's ration of

one-and-a-half tortillas is shown between them (From *Mendoza Codex*, page 59; from a photo of the codex)

Textiles in Mesoamerica, Fig. 2 A Maya almanac illustrating the goddess *Sak Na* preparing her warp (From *Madrid Codex*, page 102; drawing after Villacorta)

interpretations of the activity portrayed in this illustration, the overhead texts clearly read: *Sinah u chuch Sak Na*, or "She strings her warpboard, *Sak Na*," describing in ancient Mayan the process depicted. This manner of preparing the warp yarn, by measuring and stretching it between vertical posts on a warping frame, was in use at the time of the Conquest

and survives to this day. It is the initial phase of preparing a backstrap loom (Fig. 3) for weaving.

As the warp yarns are measured, they are wound alternately to one side and the other of a pair of vertical posts, thus creating a lease which maintains their order and allows the easy selection of alternate threads. Once wound,

Textiles in Mesoamerica,

Fig. 3 The structure of a backstrap loom, showing component parts and how they are used to create two sheds for weaving (Drawing by Carolyn Jones)

the opposite ends of the warp are secured to bars which form the ends of the loom, and a large, smooth, rounded stick (the shed roll) is placed through one side of the lease. The shed roll allows for the lifting of those threads which travel over it, one half of the total warp threads in alternating order, creating the first opening or shed. The remaining threads, which travel under the shed roll, are individually secured to a second stick (the heddle). By pushing the shed roll back and lifting the heddle, the other half of the warp threads are raised, creating the second shed. This is the mechanism by which Mesoamerican weavers created plain woven fabric.

Before the loom is ready for weaving, additional implements are required. A long, heavy, straight-sided wooden stick (the batten) which can be turned on its side to enlarge the shed through which yarn (the weft, carried on a shuttle) will pass, and which is used to beat that weft into place, is employed continuously during weaving. A thin stick (the tenter) is usually attached to the fore-edge of the weaving to regulate the fabric width. Finally, the far end of the

loom is tied to a tree or post, while the close end is attached to a strap which travels around the weaver's hips as she sits on the ground. By adjusting the position of her body, the weaver controls the tension of the warp of her loom.

This action is illustrated in the *Florentine*, *Mendoza*, *Matritense*, *Dresden*, and *Madrid Codices*, and in clay figurines from Maya burials on the island of Jaina. The *Madrid Codex* contains an almanac comprised of two episodes (Fig. 4). The first is illustrated with a crude drawing of a skirted female on her knees, her left hand supporting a backstrap loom, her raised right hand inserting the batten. Over the scene is an explanatory text that reads: *Och-i ti te' Ch'ul Na Che'el*, or "Divine *Na Che'el* (another name for the Maya weaving goddess) weaves at the post."

Simple in construction, the backstrap loom was well suited to the Mesoamerican woman's environment. Spinning and weaving were but two of her many daily chores, and the easy portability of the backstrap loom allowed its being rolled up for safekeeping when not in use, or set up when

Textiles in Mesoamerica, Fig. 4 A Maya almanac illustrating the goddess *Na Che'el* weaving at her backstrap loom (From *Madrid Codex*, page 102; drawing after Villacorta)

and where convenient. The simplicity of the equipment, however, did not preclude complex weaving. Extant fabric fragments display a wide variety of techniques. Among the simple weaves are plain, semibasket, basket, twill, and gauze. More complex weaves include supplementary weft brocade, tapestry, inlay, supplementary warp patterning and pile, warp interlock, and layer exchange double cloth (Fig. 5).

The structure of the backstrap loom determined several qualities of the fabric to be woven. The size of the finished cloth was determined when the loom was set up, and was limited in both width (by the weaver's armspan and her need to position herself at the center of the loom for proper tensioning), and length (the longer the warp, the more cumbersome and difficult it was to weave). When a large fabric was required, it was woven in small rectangles and pieced together, usually without cutting. Mesoamerican fabrics could include four finished edges and tended to show more warp than weft, with warp counts as high as 78 threads to the inch recorded.

In addition to weaving, ancient Mesoamericans were familiar with twining, braiding, plaiting, knotted and knotless netting,

sewing, and embroidery. Methods for making leather, felt, bark cloth, and paper were known. At the time of the Conquest, new materials and techniques were introduced, including needle knitting and the use of sheep wool and silk. In some areas, the treadle loom came into use, and men entered the field of textile production. These different technologies survive side-by-side with backstrap weaving today.

The importance of textiles, and particularly of weaving, to the ancient cultures of Mesoamerica must not be underestimated. Weaving was not simply a means of producing necessities of daily life, but was an expression of the Mesoamerican world view. The act of weaving was seen as a basic creative force, analogous to the original creation of the world in Mesoamerican myth. The symbolic significance of the act of weaving lives on in the complex patterns of the modern Maya woman's *huipil* (or traditional poncho-like garment), each of which is a cosmogram that places the weaver at the center of the universe. Many designs used today are notably similar to symbols depicted in carved stone representations of textiles from the ninth century, thus displaying remarkable continuity with a lengthy and rich Mesoamerican textile tradition.

Textiles in South America

Amy Oakland Rodman

Unlike most parts of the world where discoveries of ancient textiles are unusual, the Pacific desert coast and dry western Andean slopes have preserved enormous quantities of textiles, wood, feathers, plant material, and other usually perishable artifacts. Most of the best preserved textiles were originally part of burial furnishings left in ancient cemeteries stretching from central Peru to northern Chile. The far north Andean coast (modern Colombia, Ecuador, and northern Peru) encounters periodic torrential showers which have destroyed most ancient remains. Few textiles have survived from the highland wet and dry climate or the rainforest regions of the eastern Andean slopes stretching to the Atlantic ocean.

It is apparent that desert conditions and the careful preparation of tombs are the two elements

most responsible for the preservation of ancient Andean textiles. Beginning around 3200 BCE and continuing until the conquest of the Andes in AD 1532, it is possible to reconstruct textile technology in coastal regions and occasionally to witness highland development through textiles preserved in coastal sites.

Archaeologists have designated the Cotton Preceramic (3200–1800 BCE) as a period when a variety of coastal cultures developed cotton twining, looping, and other nonloomed textiles before the use of the heddle loom or ceramics. Major discoveries at Huaca Prieta, La Galgada (a highland site with remarkable preservation), and in Asia have determined that not only were large quantities of cotton textiles used, but that some were elaborately patterned. Images on Preceramic cotton textiles include condors with outstretched wings, two-headed snakes, and humans or deities with splayed feet, all subjects with similar presentation to images which continue in the art of many subsequent Andean cultures. Designs are created through transposing twined elements, often combining a change in regular yarn movement with alternating colored yarns. Cotton dyes include indigo for blue and unidentified, red, yellow, and brown colors. Thicker plant fibers were twisted into sturdy twined mats, while cotton was used for looped caps and twined mantles.

Beginning in the Initial Period (1800–800 BCE) and the following Early Horizon (800–0 BCE), Peruvian textiles developed through the use of the heddle loom. Hundreds of painted Early Horizon cotton plain-weave textiles discovered near Karwa on the Peruvian south coast identified fabrics with designs very similar to stone carvings from the north highland pilgrimage site of Chavin de Huantar. This important and well-preserved painted ritual cloth provided evidence of the ways in which textiles were used to transport religious imagery throughout the Andes beginning in very early periods.

Camelid fibers, sometimes termed “wool” yarn, from the hair of the nondomesticated guanaco and vicuna or the domesticated llama and alpaca, were introduced into coastal weaving

during the Early Horizon. Camelid hair is more easily dyed than cotton and its introduction into coastal technology is usually based in its application in brilliant colors for weft-patterned structures. The first all-wool tapestry textiles appear in coastal cemeteries during this period and it is likely that these identify an ancient highland wool technology rarely preserved in the highland regions of natural camelid habitat.

The famous Paracas textiles were woven and embroidered on the southern Peruvian coast during the Early Horizon. On the Paracas Peninsula, elite individuals were buried with hundreds of embroidered shirts, skirts, mantles, feather fans, and golden objects all wrapped inside enormous plain woven cotton winding cloth. The multicolored wool embroideries depicted repeating human, deity, and animal images and were executed in stem stitch on plain-woven fabric. Paracas textiles also included a unique type of three-dimensional embroidery using the cross knit loop stitch to embellish borders with polychrome images. The technique was created with a single cactus spine needle as a continuous form of crossed looping.

The Nazca culture, which followed the Paracas on the south coast in the following Early Intermediate Period (AD 0–500), continued one of the most elaborate weaving technologies ever known, with textiles in double and triple cloth, warp and weft patterning, oblique interlacing, and fine garments woven with both discontinuous warp and weft. Andean loomed textiles are characterized in their tradition of four finished selvages. Individual finished cloth webs were sewn together to complete a garment and were rarely cut.

Very little is known of north coast weaving during the Early Intermediate Period, the time of Moche cultural development. The few surviving Moche textiles identify a technology principally based in the use of cotton and a narrow backstrap loom like that employed on the south coast. But structurally, Moche textiles are distinguished through the use of fine un-ply cotton yarns in twilled and weft-brocaded structures. Moche tapestry is woven with both cotton and dyed camelid fiber weft over a cotton warp using a

non interlocking weft which creates vertical slits between different color areas. Apparently slit-tapestry was common to coastal cultures both north and south.

Although known for only a handful of large weft-interlocked tapestries or tapestry fragments and triple-cloth narrow bands, the Early Intermediate Recuay culture of the Peruvian north highlands developed a distinctive textile tradition. Recuay tapestries were woven on a wide loom of more than 7 ft with a short warp of no more than 2 ft. Brilliantly dyed red and yellow wool yarns are characteristic of Recuay textiles, and tapestries use the highland weft-interlocked structure which leaves no openings between areas of different color. In the south central Andes, weft-interlocked tapestries uncovered on the Chilean north coast have been attributed to the Alto Ramirez culture of the southern highlands. Alto Ramirez textiles exhibit a decided preference for the use of blue and red dyed yarns almost certainly identifying an ancient source and knowledge of indigo dyeing in the southern highlands.

The following Middle Horizon (AD 500–1000) marks a break with previous cultural development. The Peruvian Huari culture located near the modern city of Ayacucho appears to have controlled the central Andean highlands and coast, while the south central Andes was allied to the site of Tiwanaku. Tapestry was the distinctive Middle Horizon medium woven in slit techniques with cotton on the coast and with interlocking camelid fiber wefts in the highlands. Local, coastal tapestry continued to be woven on the narrow backstrap loom. Highland Tiwanaku and Huari tapestries preserved in coastal desert burials identify the use of the wide loom with narrow warp like that used in Recuay tapestry. Huari shirts were woven in two parts and seamed down the center leaving an opening for the head and neck. The few Tiwanaku shirts discovered in northern Chilean desert cemeteries were patterned with similar images but were woven in a single panel with a neck opening woven through discontinuous wefts. Headgear was always used as an important Andean badge of identity. Huari and Tiwanaku

officials wore a knotted hat with four peaks or points on the top. Tiwanaku four pointed or cornered hats created polychrome designs in lark's head knots while similar Huari hats were patterned with knots with tufts of wool pile in each knot.

By AD 1000 the highland centers of Huari and Tiwanaku had collapsed and individual cultures began clearly to establish local identities noted in regional textile styles. Warp-patterned structures such as complementary and supplementary-warp weaves were commonly woven in the following Late Intermediate Period (AD 1000–1450). Textiles are often characterized as having repetitive, small-scale imagery in gauze, painted cotton, weft-brocades, and double-woven fabrics. South coast weavers shaped bags and shirts through the selective addition of warp yarns during the construction process. North coast weavers often wove exotic bird feathers into the cloth, creating shirts and other garments with one face completely covered with feather patterns. During this period coastal weaving especially exploited the full potential of natural native colored cottons which were woven in contrasts of white and natural red-brown, beige, and grey.

The highland Aymara weaving tradition was consolidated in the south central Andes during the Late Intermediate Period after the fall of Tiwanaku. Aymara textiles are characterized by elegantly striped warp-faced shirts, woman's dresses, head cloths, and mantles in natural colored camelid fiber yarns often dyed blue, green, and red.

The Late Horizon (AD 1450–1534) again marks the period when local cultures were brought under highland control, this time that of the monolithic Inca state with its capital at Cuzco in the southern Andes. Inca textile patterns are strictly geometric and nonfigurative and the most valued cloth was weft-interlocked tapestry woven on the wide tapestry loom with a short warp. Some of the best preserved Inca textiles have been discovered as miniature offerings covering gold and silver male and female figurines and left on the tops of Andean mountain peaks from Ecuador to Argentina. Male garments include a tapestry tunic, a mantle, a bag with a

carrying strap, and a large feather headdress. Female garments include a large wrap-around dress and a narrow, highly patterned belt. Most of these garments are woven entirely in camelid fiber and are colored with red and yellow dyes.

Following the conquest of the Inca state by European conquerors, European methods of textile manufacture were introduced throughout the Andes. The spinning wheel was adopted for workshop production, and the treadle loom was constructed for the manufacture of yardage to be sewn into non-Andean style tailored clothing. Needle knitting was introduced and is now regularly used for sweaters and knitted caps in local communities. Felting was introduced for wide-brimmed hats which have now become part of indigenous community dress in many regions.

While foreign clothing styles and techniques replaced local garment manufacture in coastal regions, European methods never replaced highland traditions in many indigenous communities in Colombia, Ecuador, Peru, and Bolivia. Today, some areas have maintained camelid-fiber spinning practices using the drop spindle and the backstrap loom or the staked ground loom to produce native four-selvedge garments. Men are the principal weavers in indigenous communities in Colombia and Ecuador, and women weave in Peru and Bolivia. In the southern Andes men weave on the European treadle loom. All community members spin, but spinning is generally considered women's work. Many communities continue to express local identities through handwoven patterns and specific color combinations which are worn daily or for community rituals. Traditional four-selvedged handwoven garments are also worn with European-style vests, pants, sweaters, or skirts in many areas. Some communities have specialized in the decoration of textiles with sewing machine embroidery.

Outside of the Andean region, a few Brazilian tribes and groups living in the Amazonian areas of Ecuador, Peru, and Bolivia, have continued lowland traditions using barkcloth, elaborate feather headdresses, and oblique-interlaced bags and narrow bands, textile traditions which may reflect ancient lowland origins never preserved in these wet regions.

South America continues as the native home to herds of guanaco, vicuna, llamas, and alpacas with an export industry in camelid fiber and manufactured textiles. Peruvian cotton is valued for its luster and is enjoying a revival in interest in native natural-colored cotton yarns.

Thābit ibn Qurra

Boris A. Rosenfeld
PA, USA

Abū'l-Ḥasan Thābit ibn Qurra ibn Marwān al-Ḥarrānī al-Ṣābi' (836–901) was a Syrian mathematician, astronomer, physicist, physician, geographer, philosopher, historian, and translator from Greek and Syriac into Arabic. His scientific treatises were written primarily in Arabic and partly in Syriac. He was born in Kafartūtha near Ḥarrān (now Altınbaşak in Southern Turkey) and was a student in Ḥarrān. Ḥarrānians, the descendants of the ancient nation Mitanni in the Hellenistic age, were Hellenized, and their ancient religion of star worship was deeply connected to Greek philosophy. In the Arab caliphate,

Ḥarrānians called themselves Ṣābians since the Ṣābian religion was one permitted by the *Qur'ān*. Ḥarrān University was founded in the fifth century in Alexandria as a school of philosophy and medicine. After the Arab conquest, it was moved to Antiochia and later to Ḥarrān where, under the influence of Ḥarrānian traditions, astronomy and mathematics were taught, and it became a university.

At first Thābit ibn Qurra worked in Kafartūtha as a money changer. Here the Baghdad mathematician Muḥammad ibn Mūsā ibn Shākir met him and invited him to Baghdad, where Muḥammad and his brothers Aḥmad and al-Ḥasan, the Banū Mūsā, became his teachers. Later he worked at the court of the caliphs in Baghdad and in Surra man ra'a (Samarra) as a physician and astronomer. His position as the caliph's physician allowed him to keep his heathen religion. His son Sinān ibn Thābit and grandson Ibrāhīm ibn Sinān also were mathematicians, astronomers, and physicians in Baghdad.

Thābit ibn Qurra's contributions to science covered many different disciplines, from mathematics to philosophy. In mathematics, he was a translator or editor of translations of many works of Euclid, Archimedes, Apollonius, Theodosius, and Menelaus. Many of these are extant only in these translations. These translations, together with the geometric treatise of Thābit's teachers, the brothers Banū Mūsā, and his *Kitāb al-mafrūdāt* (*Book of Assumptions*), constituted the so-called middle books which were studied between Euclid's *Elements* and Ptolemy's *Almagest*.

Two of Thābit's treatises on parallel lines were first written in Syriac, the first under the title *Ktovo al-hay da-tren surte trishe kad mettapkin al bshir men tarten gonowoto dag'in bahdode* (*Book [in which is proved] that Two Lines Produced Under Angles Which are Less Than Two Right Angles Will Meet*). The second is called "the second book on the same topic." Both these treatises are extant only in the Arabic translations made by Thābit himself. The ideas of these treatises were further developed by Ibn al-Haytham (965–ca. 1050), 'Umar al-Khayyām (1048–1131), and Naṣīr al-Dīn al-Ṭūsī

(1201–1274) and later led to the discovery of non-Euclidean geometry.

Thābit's *Kitāb fī ta'līf al-nusub* (*Book on Composition of Ratios*) was devoted to the theory of compound ratios. This theory later led to the notion of real numbers and to the discovery of differential calculus.

Other works covered such subjects as a simple proof of the Menelaus theorem (the first theorem of spherical trigonometry), mensuration of plane and solid figures, and solutions of different problems of integral calculus. His books contained some proofs of the Pythagorean theorem and its generalization and dealt with the subject of amicable numbers, in which each number is equal to the sum of the divisors of the other.

In the field of astronomy, Thābit was the editor of the translation of Ptolemy's *Almagest* and the author of many treatises on the movement of the sun and moon, sundials, visibility of the new moon, and celestial spheres. In his treatise "On the Motion of the Eighth Sphere," extant only in Latin translation (*De motu octave sphere*), he added the ninth to Ptolemy's eight spheres and proposed the theory of "trepidation" to explain the precession of equinoxes. The fragments of Thābit's Syriac *Ktovo d'pulog d'yumoto d'shobo'o al koukbe shab'e* (*Book on the Subdivision of 7 days of the Week According to Seven Planets*) are extant in Bar Hebraeus' *Chronography*. In this book, the planets are designated by their Babylonian and Greek names; this subdivision was known to Romans and Indians and is the source of the names of the days of the week in many European and Asian languages.

Thābit also wrote books on mechanics and physics. His *Kitāb al-qarashūn* (*Book on Lever Balance*) discusses the conditions for equilibrium of different kinds of levers. In his *Kitāb fī masā'il al-mushawwiqa* (*Book on Interesting Questions*), Thābit tries to explain the phenomenon of the camera obscura. This attempt was erroneous, but it led Ibn al-Haytham in the *Book on Forms of Eclipses* and al-Bīrūnī (973–1048) in *The Exhaustive Treatise on Shadows* to the solution of this problem. He also studied the problems of acoustics in *Mas'ala fī'l-mūsīqā* (Question on

Music) which is an extant fragment of his great *Book on Music*.

In geography and medicine, Thābit revised works of Ptolemy (*Kitāb ṣūra al-arḍ*, *Book of the Picture of Earth*) and Galen. He was the author of the fundamental *Kitāb al-dhakhīra fī 'ilm al-ṭibb* (*Book of Treasure in the Science of Medicine*).

In philosophy, Thābit emphasized that integer numbers were abstractions of objects of counting and criticized Aristotle who rejected actual infinity. In his commentaries to Aristotle's *Metaphysics*, he considered the problem of the "first motor" and argued with Aristotle's opinion that the essence is immobile. Many of Thābit's treatises are devoted to problems of religion, in which he is critical of both Christianity and Islam.

Timber-Handling Technology in Japan

Conrad Totman

Japan has long been known for the ability of its artisans to construct gigantic, durable wooden structures, lesser wooden buildings of graceful design, and small objects of meticulous craftsmanship. One wonders how they were able to use the trees of their archipelago for these purposes when its topography made logging and timber transport so exceedingly difficult.

Preindustrial Timber Handling

Japan's earliest wood-handling technology was predictably simple. Stone – and later metal – hand axes, adzes, and chisels were used to fell and process tree trunks and ► [bamboo](#) to create rafts, dugout canoes, and plank-walled boats;

diverse hand tools, weapons, and other small objects; and post-and-beam buildings lashed together with vine and enclosed with thatch or wattle.

During the seventh century, however, major new architectural forms – grand wooden palaces and Buddhist temples that utilized stone foundations, mortis-and-tenon framing, board walls, and tile roofs – arrived from the adjacent continent. These new forms vastly increased the demand for timber and, as a consequence, produced changes in all stages of wood handling, from felling and transporting to final fashioning into the devices of daily life. In following centuries that technology was elaborated and refined, and its usage spread across the islands.

In the first stage, loggers used slender-hafted, narrow-bladed axes to fell and limb trees and cut them to length. By the sixteenth century blacksmiths were producing large saws with sufficient temper and consistency of thickness for use as crosscut saws, and for several decades woodsmen employed them in felling trees. During the seventeenth century, however, their use for felling was outlawed, evidently to prevent timber theft: the sound of an axe thwack carries much farther than does the swish of a saw, helping guide warden to miscreant. From then until the late nineteenth century felling was handled by professional axmen. To facilitate the felling of especially large trees, choppers gouged holes around the base, stuffed the wood chips back into them, and set them to burning, guiding the burn through the base so as to fell the tree in the desired direction.

Turning to transportation, in early centuries, when adequate timber was available within reasonable proximity of a construction site, logs could be carried to it on two-wheeled oxcarts. Or they could be floated downriver (or hauled upstream by man or animal power), snared and pulled ashore at a landing, and then loaded onto carts for overland transport.

Later, as lowlands were cleared and more and more timber came from steeply mountainous regions, the transport system became more complex. Skidding crews at the felling site used long-handled hooking tools, vine or woven rope, and,

where the situation required them, winches and sleds to role, skid, and sled pieces down to a log-assembly point. There (or sometimes at the felling site) axmen hewed the logs to form roughly rectangular pieces. This hewing reduced log weight, rendering sticks more manageable, and it made them more stable for the journey to town. In particular, when used to form rafts, hewn pieces were far less likely to twist and tear apart as raftsmen were negotiating rapids and turns in the river.

Depending on the terrain, workmen might use some of their squared sticks to form log trestles or trough-shaped chutes down which they could slide pieces to streamside. Or in the case of assembly beside a small mountain stream, they could construct splash dams and elevated chutes as needed to propel sticks on the flood down to where normal stream flow would float them freely.

Where felled trees were being converted to shingling or other small pieces, they commonly were split to portable size at the felling or assembly site or at a river landing. And material for conversion to charcoal was processed in kilns and the cooled charcoal bagged for transport. Both split pieces and charcoal were then carried overland to market by packhorse or floated out of the forest aboard log rafts.

The trip by water could be complicated. Most of Japan's rivers rush from mountains down to the sea, and given the frequency and unpredictability of downpours, freely floating logs risked doing damage to riverbanks or facilities, being stranded by high water at inaccessible sites, or even of floating out to sea and being lost. At convenient locations, therefore, river transporters constructed floating booms by lashing bamboo or logs together with vine and anchoring them to rock outcroppings, trees, or huge posts as the site allowed. These booms captured floating sticks, enabling workmen to beach them for temporary storage or processing or to assemble and bind them into rafts for the remainder of their journey.

On the largest rivers, the short initial rafts were beached at a midway point and several then joined end-to-end for the journey's final leg to a landing near the coast. At seaside, especially

large logs could be lashed to shipside or hauled astern to a port of destination. But most pieces were taken aboard for the trip.

At the lumberyard or work site, squared logs were left floating in the water until needed, or they were stacked on land for curing and sale or processing and use. To convert a log to boards or planking, sawyers positioned one end on a high A-frame and used wide-bladed saws to rip it to the specified dimensions. The saw teeth were shaped to cut on the draw stroke rather than the push stroke, which reduced the risk of kinking the blade. That design lowered the required level of temper and hence the cost of the saw, but it increased the frequency of sharpening.

Other workmen used regular axes or broad-axes to split sticks into staves, shingles, or fuel wood. And carpenters and craftsmen employed a handsome array of hammers, small saws, adzes, planes, chisels, rasps, and drills to shape pieces for final use, whether as building parts, cabinetry, tools, weapons, *objets d'art*, or whatever.

By the nineteenth century, then, Japan had a well-developed and complex system of wood provisioning. It was operated by an array of professionals – axmen, skidders, raftsmen, other rivermen, sawyers, and carpenters – most of whom were organized in guilds that protected their fields of expertise and employment. And timber merchants, who arranged and financed many of the logging and transport operations, also managed the lumberyards and handled most of the wholesaling, jobbing, and venture capitalization that the timber business entailed (Figs. 1, 2, and 3).

Industrial-Age Timber Handling

The world of preindustrial timber provisioning was thrown into turmoil during the 1860s when the established political order collapsed in the face of foreign encroachments. The new rulers set out to achieve rapid national self-strengthening, and that project entailed, among other things, sharply intensified exploitation of domestic resources, woodland included.

Timber-Handling Technology in Japan,
Fig. 1 Stacking wood at a lumberyard on Tatekawa Canal in a harbor side section of Edo (today's Tokyo). Men on the *left* stack split pieces of fuel wood; bales of charcoal are stored under thatch cover at their feet; sawyer

on right rips a timber to form planks; poles are stacked vertically to his *right*, partially obscuring Mt Fuji; plank-ing, boards, squared timbers, and long green bamboo poles are below him (Katsushika Hokusai, *Thirty Six Views of Mt. Fuji* (ca. 1820), in the author's possession)

Timber-Handling Technology in Japan,
Fig. 2 Sawyers rip a squared timber at Yamanaka in Tōtōmi Province, southwest of Mt Fuji, while another workman, seated before their temporary mountain hut, sharpens his saw, as family members look on. (Katsushika Hokusai, *Thirty Six Views of Mt Fuji* (ca. 1820), in the author's possession)

Those developments altered radically the techniques of felling, transporting, and milling timber.

Until around 1900 the organized guilds of axmen, raftsmen, and others were able to slow appreciably the inflow of new technology. But by then the use of crosscut saws – no longer

forbidden after 1868 – had become common, and they prevailed into the 1950s, until being displaced by chain saws. And in those areas, mainly in Hokkaido, where tractor-mounted mechanical saws are able to function, they and other similarly “high tech”

Timber-Handling Technology in Japan,

Fig. 3 Surrounded by his mallets and bamboo for hooping, a barrel maker smooths the inner surface of his staves at Fujimigahara in Owari Province, west of Mt Fuji (Katsushika Hokusai, *Thirty Six Views of Mt. Fuji* (ca. 1820), in the author's possession)

devices – feller-bunchers, skidders, processors, harvesters, forwarders, and tower yarders – have been introduced during recent decades in unsuccessful attempts to reduce labor costs enough so that the domestic timber harvest can compete with imports.

Rather similarly, raftsmen and rivermen retained their roles until around 1900, when timber began leaving the forest by tramway and railroad. By the 1930s nearly all flotation and rafting had ceased. But starting then, and especially after 1950, rails in turn gave way to roads as trucks and “Caterpillar” type tractors and sleds took over. In some interior valleys, moreover, highlines have come into use for carrying logs airborne from felling site down to assembly point, where they are yarded and loaded onto trucks or otherwise moved along for processing.

Sawmills had appeared in Japan by the 1870s, initially sash saws (vertically mounted, mechanically powered crosscut saws), subsequently circular saws, and eventually band saws (continuous ribbons of toothed steel driven at high speed by sheaves mounted above and below the saw carriage). The earliest were water and steam powered, but electric power, whether purchased or produced on site, came to prevail during the early 1900s. And internal-combustion engines later powered some portable mills. (Pulp,

plywood, and chip mills, technologies that are not discussed here, were introduced to Japan, respectively, in 1886, 1907, and 1957.)

The scale of Japan's sawmill technology has differed greatly from that found elsewhere. During the years ca. 1860–1920 the productivity of mills in Euro-America rose dramatically, tenfold or more. That rise was made possible by myriad technical improvements in saw types, power sources, and other aspects of mill equipment. But it also was premised on two conditions not found in Japan.

First, it presumed the existence of sprawling, richly stocked, flatland forests cut by leisurely flowing rivers that could float vast quantities of large, same-species logs to a sprawling sawmill site, flatland that would, a few decades later, provide easy terrain for the construction and use of roads and railways. Second, it presumed a system of woodland ownership that would allow a mill to obtain vast quantities of logs from large, more-or-less contiguous areas. In Japan, however, nearly all forests were on steep mountainsides, and possession was highly fragmented, about half being owned by smallholders with a few acres apiece, the other widely scattered half by government. Almost nowhere could a mill operator expect to obtain substantial quantities of large-scale timber from his immediate

environs for any extended period. In consequence, before World War II the most efficient technology did not fit Japan's circumstances, and the newest devices, band saws most importantly, were used in only a small portion of the country's sawmills.

During the first two decades after that war, great effort was made to introduce and refine the most up-to-date mill technology. However, from about 1970 onward, imported wood undermined the profitability of domestic milling, and the enthusiasm for technological change largely evaporated. Instead, sawmills gradually developed in two directions. Today large, highly integrated mills, which are set up at coastal sites near major markets expressly to handle imported logs, use elaborate, efficient, high-speed equipment to produce great volumes of lumber. Domestic timber, meanwhile, is mostly sawn at small mills set up in major timber-producing areas, where they use much simpler equipment to turn out high-grade, specialty lumber, but at rates comparable to those of American sawmills of the 1860s.

So today the timber-processing technology of Japan is used primarily to handle imported wood. And that situation seems likely to prevail for a few more decades, until destruction of the world's woodland drives global timber prices up enough to make Japan's mountain forests again competitive in the marketplace.

Time

Henry J. Rutz

The dual classification of cultural systems of time as Western or non-Western is an oversimplification that limits our understanding of how time is created, represented, measured, and practiced in different cultures. The premises underlying dualistic thinking about time reveal its limitations.

First, dualistic thinking adopts the premise that Western time is linear (irreversible), abstract, quantitative, and homogeneous. In contrast, non-Western time is cyclical (reversible), concrete, qualitative, and heterogeneous. There is a tendency to draw too sharp distinctions based on characteristics presumed to be in opposition. Underlying these are further distinctions between *them* (Oriental, primitive, oral, preindustrial) and *us* (Occidental, modern, literate, industrial). Embedded in these implicit distinctions is the assumption that non-Western time is to be thought about within a conceptual frame that implicitly adopts Western time as a standard for perception and evaluation of non-Western time. In a word, dualistic thinking about time has been Eurocentric.

Second, dualistic thinking rests on the premise that Western and non-Western cultures are different and unrelated totalities, and that time is unitary within each. The Unitarian premise leads to generalizations such as believing that non-Western cultures have a cyclical as opposed to a linear concept of time. The result is that diversity is underreported and undertheorized.

Third, dual systems of culture and time suffer from an ahistorical and overly formal foundation to knowledge. Western societies have "history" and a consciousness of being in time, in contrast to non-Western societies which have "myth" and a sense only of relational time that renders events mere epiphenomena of structure. Myth is not about the causation of before and after but about a formal means for making all the elements and characters ever-present.

Fourth, the ahistoricist premise also leads to the view that non-Western societies have an awareness of themselves in time only to the extent that westerners bring such awareness to them, either in the form of historical consciousness or as a practical matter of the efficient and productive use of time as a resource.

Fifth, dualistic thinking rests on the premise that time is a thing that is either present or absent in a culture. A dichotomy between western *linear* time and non-Western *cyclical* time appears as real and coerces people to behave and think in a particular way. But the terms of this dualism are highly abstract and refer to no particular period, bounded space, social organization, or real people. The dichotomy bears little relation to the cultural construction of time in the everyday lives of people in a specific region, a particular period, or known conditions of migration, diffusion, and contact.

The situation is complex. While no cultural constructions of time have remained unaffected by European expansion, it is presumptuous to think that we know what aspects of European time (which varied in different periods and places) influenced a bewildering variety of religious communities, empires, and kin-ordered societies, each with its own historically constituted temporal rhythms. Indeed, examining the real complexities of culture and history raises important issues about temporal dynamics only to the extent that we abandon dualistic thinking.

An alternative perspective, one that anthropologists, historians, and archaeologists increasingly embrace, pays attention to multiple constructions of time in single social formations, the extent to which different times are articulated, and the temporal dynamics of development and change in the rhythms of everyday life.

While some languages lack a generic word for time, there is abundant evidence for the universality of concepts of duration and succession in the linguistic and cultural practices of every person. The French sociologist Émile Durkheim expressed the opinion that it is hardly possible to think about time "... without the processes by which we divide it, measure it or express it with

objective signs." These processes, he concluded, are social in origin. The anthropologist Edmund Leach, following Durkheim's lead, noted that "We talk of measuring time, as if it were a concrete thing waiting to be measured; but in fact we create time by creating intervals in social life. Until we have done this there is no time to be measured." To these ideas about time we need to add those of another French sociologist, Georges Gurvitch, who pointed out that every social formation has a multiplicity of times. Not only are there different collective representations of time among different cultures, but different time systems coexist within a single social formation.

These ideas, that time is culturally constructed, socially embedded, and multiple, have become guiding principles in cultural studies of time. The other articles on time in this encyclopedia illustrate the complexity and diversity of time systems from the multiplicity of time perspective. A brief comment on a number of issues will clarify the present direction in cultural studies of time systems.

1. Acceptance of the multiplicity of time within single social formations has led to the rejection of attempts to classify whole societies, not to mention a whole class of societies such as "Western" or "non-Western" by any single subsystem of time. Comparison remains important, but comparativists now recognize that they must seek out similar subsystems in different cultures. Leopold Howe, for example, disputes Clifford Geertz's conclusion that the Balinese calendrical system does not represent a flow by which the passage of time can be measured, that the calendar represents a concept of time that is nondurational, and that Balinese experience of time is of "islands" or points that are unconnected (an extreme form of discontinuity, imprecision, and noncountability). Geertz asserts that the particulate nature of days implies a nondurational concept of time. Such a description of Balinese time carries an implicit comparison with our own, based on dualistic assumptions that go unexamined in both. Howe provides

evidence that Balinese count days and are forever referring to past and future in terms of such counts. Geertz confused an attribute of members of a class with the class itself—each day is qualitatively different from others, but days fit into a succession that is endlessly repeated. Each name day partakes of being a day that *qua* day has the attribute of countability. The Maya had no such confusion. They viewed time as a flow that could be measured and also endowed days with qualities dependent upon the work of gods and men.

2. Recognition of the multiplicity of time shifts attention away from gross comparisons of presumed-to-be-different systems of time toward contextualized descriptions and similarities of subsystems in apparently different cultures. There has been a concomitant shift from classification to process, raising questions about temporal dynamics. How *does* time get constructed? What *are* the processes of development and change that account for the multiplicity of time and the degree of articulation among subsystems? Cultural studies of time have taken several directions, none of which is mutually exclusive. Nancy Munn challenges, from a phenomenological perspective, Evans-Pritchard's conclusion that Nuer time amounts to a creation of a static and nondevelopmental experience of time. His structural models of Nuer time overlook Nuer accounts of their bodily activity of procreation, their own subjective experience of time in terms of layers of ash on the fires, their ability to plan for events in the future, and other evidence of developmental constructs of time in their projects and practices. Peter Rigby, who has researched the age-set system of the pastoral Ilparakuyo Maasai in Kenya, challenges, from a historical materialist perspective, Evans-Pritchard's failure to address the degree of articulation of Nuer multiplicity of time. Had Evans-Pritchard taken into account the historical consciousness of Nuer, he would have found that all the elements of time-reckoning can be placed in a single conceptual frame arising from the historical development of Nuer within a specific social formation. Rigby, drawing on his own work and that of others, attempts such a synthesis for the Ilparakuyo Maasai.
3. Cultural studies of time that explore the underlying temporal dynamics of how a multiplicity of time is constructed have paid increasing attention to the politics of time. Cultural constructions of time are part of the political economy of development. The creation of time requires agents and agencies temporalizing their respective projects in struggles for power and legitimacy. Farriss' attempt to reconcile cyclical and linear concepts within the same calendrical system in Maya culture rests on an interpretation of Maya political transformation from city-states to rule by dynastic lineages. With the demise of Maya elites, subsystems of time wither and die.
4. The attention paid to the politics of time has raised anew issues about the reflexive study of time in different cultures. Johannes Fabian has criticized anthropologists for failing to recognize that theories which distance "other" cultures by placing them in an-other time unwittingly use time as an instrument of political domination. Apparently disinterested studies of difference are revealed to be interested studies of "the other", a form of cultural politics. The solution is to recognize that people of different cultures are contemporaries and use that as a point of departure for all conceptual frames concerning the politics of time. A reflexive approach to cultural construction of time would overcome Rigby's concern that most descriptions of time in "different" cultures are really implicit comparisons using hegemonic bourgeois time as a standard. Most of us reckon time in our daily lives by systems other than the formal-mathematical or chronological ones deployed by an army of scientists, historians, and anthropologists. Such reflexivity, or self-awareness, of our own multiple concepts of time would be salutary for advancing our understanding of the cultural construction of time in different cultures.

Time in Africa

Henry J. Rutz

In every society, one source by which time is divided, measured, and expressed by objective signs is the mutual obligations and principles that structure social relations between persons and groups. Among the most important is kinship. In those societies in which kin communities encompass the widest range of social relations, time is expressed as duration and succession of kin-ordered activity. Perhaps the best-known case is that of the Nuer, a Nilotic pastoral people who live in villages of the upper reaches of the Nile in Sudan.

E.E. Evans-Pritchard has given us a rich account of ways in which village kin communities conceptualize and reckon time as an aspect of social structure. Among the multiplicity of times

apprehended by Nuer, three of the most important subsystems are (1) a series of social activities articulated with a series of ecological events by which one is used to measure the duration and succession of the other; (2) a series of age-sets that measures intervals and succession in the life cycle; and (3) a hierarchy of segmented kin groups that measures lapsed time, i.e., a form of collective memory of the “past” that constitutes the conceptual frame of Nuer history.

Nuer livelihood is based primarily on cattle herding and the cultivation of millet, a dual adaptation to vast stretches of marsh and savannah in a climate that necessitates a transhumant existence between village settlements on knolls during the rainy season and dry season cattle camps near rivers. A change of season is the objective sign for a change in settlement pattern, accompanied by changes in ceremonial and social activities. Most collective rituals, such as marriage and male initiation, take place in wet season villages, but the dry season cattle camps, when youth disperse to small camps in search of pasturage near sources of water, are viewed as a time of freedom and courting. In a rare comment on the experience of seasonal rhythms, Evans-Pritchard states that the pace of time speeded up during the wet season and slowed down during the dry season, an effect of the density of social activities and the significance the Nuer attributed to them.

Although the Nuer have no word for a generic “year”, they reckon cycles of wet and dry seasons, giving names to each, and divide the cycle into 12 named “moons” of unequal duration that mark the succession from wet to dry season and back again. The duration of months depends less upon lunar observance (though they are familiar with phases of the moon) than the agricultural and pastoral activities associated with ecological phases within seasons. Nuer adjust the series of ecological activities to fit social contingencies. If the Nuer were still in their dry camps, waiting for rain, then they would say that they were still in the named “moon” prior to the onset of rains. If they were still engaged in rituals associated with the wet season villages, then they would reckon the name of the moon by the social activities

appropriate to it. The result is an annual calendar embedded in a coordinated parallel series of ecological and social rhythms, the durations of which vary within and between cycles. Working one series against the other, Nuer rename months, skip months altogether, or even omit “years” in their recounting of socially significant events over a number of seasonal cycles.

Nuer can count seasonal cycles, months, and days (there is no “week”), but they tend not to. Chronology or a sense of lapsed time with respect to livelihood is culturally suppressed, giving the illusion of endless recurrence. Days, months, and seasons remain socially embedded and unarticulated as an abstract and numerical system independent of the concrete activities that lend the system meaning. The Nuer have no generic word for time.

Biological facts of individual maturation and aging, like ecological and physical facts, are given social significance in every society. But their division, measurement, and expression in objective signs are contingent and vary from one society to another.

Among Nuer, the reproduction of cattle, or cattle genealogies, is the basis of a concept of male personhood. Individual Nuer men are fiercely egalitarian and quick to defend themselves against perceived affronts to their manhood. The natural reproduction of cattle, combined with a culturally constituted series in the life cycle of male individuals—for example the transition from boyhood to manhood marked by the gift of a first cow, the transition to husband marked by a gift of cattle at marriage (a transfer from the groom’s to the wife’s kin), and a further transfer of cattle marking the transition to “fatherhood” with the birth of each successive child – regulate the rhythms of interpersonal kinship, articulating the pedigree of specific cows with the genealogy and life history of individuals.

Cattle genealogies mark the passage of time in the lives of individual male Nuer, a process that in its very nature is directional and irreversible. But Nuer also have organized individual male maturation as a collective problem of social significance. Village boys of comparable age

(between 14 and 16 years) are initiated into a named age-set during an open period. A “Man of the Cattle” is responsible for closing a period, “thereby dividing the sets.” The initiation consists of a painful ritual whereby each boy is cut to the bone across the forehead six times, producing deep scars called *gar*. His reward is a gift of his first cow and a taboo on milking. The only point of articulation between the seasonal and age-set time systems is the timing of the initiation, which occurs at the end of the wet season when food is plentiful. Proximate villages tend to coordinate periods despite independent declarations in each. Regions tend to share at least some age-set names (but vary the sequence), which differ from one part of Nuerland to another.

In pastoral Kenya and parts of Bantu East Africa, the age-set/generation-set system consists of age-sets organized into three distinct generation-sets of boys, warriors, and elders, with a pronounced taboo on warriors marrying. It is hard to avoid the conclusion that Nuer age-sets have something to do with the collective control of elders over young men. The military and administrative functions of Nuer age-sets, however, are attenuated and appear to have more to do with regulating the domestic obligations of manhood.

Nuer conceive of the age-set system as fixed at six living sets. Using a kinship idiom, they break the sets down into “brothers” who are equals, “fathers” who are elders in authority, and “sons” over whom they have authority. But age-set names are not repeated and Nuer do not perceive the age-set system as cyclical (some Bantu groups do). Age-sets whose members have died are not remembered or recounted. Even when a few old men of the most senior age-sets are still alive, junior age-sets are merging them with members of adjacent age-sets. The system is designed for the living, intended to mark lapsed time by the intervals between open and closed periods that define the age of one group of males relative to another in a weak form of gerontocracy. Like individual biography inscribed in cattle gifts and their genealogies, a sense of an irreversible flow of time is given in the fact that a named age-set “changes its position in relation

to the whole system, passing through points of relative juniority and seniority.”

All human communities develop collective representations of a past that embody a historical consciousness of the community *qua* community. Nuer have embedded their sense of historical consciousness in a model of a lineage system that creates the illusion of a fixed temporal horizon to events such as migration, tribal war, and territorial expansion that might otherwise be perceived as a succession of unique events in an irreversible “before and after” construction of past and future. The correct view of Nuer history is that it is ever-present and performative in the reciprocal rituals of lineage segments.

The segmentary principle of membership in a Nuer lineage is common descent through males from a recognized ancestor. The way Nuer think about tribal history is structured by how they think about the hierarchical relations between lineages, which also form the basis for claims to a division of territory. Reckoning political relations by lineages is relative because it depends on the particular person who is selected as the point of departure in tracing descent. The largest lineages, those which incorporate the widest latitude of members connected by descent from a common ancestor, are termed clans, and they in turn are comprised of lineages with several lines, each of which is a smaller lineage tracing descent through less distant ancestors to incorporate a narrower range of members.

The lineage system is employed by living Nuer to reckon their common past. Although every man is a potential founding ancestor, the social fiction is that the living are organized into segments in such a way that there are only 10–12 ancestors at the maximum social distance, and 3–4 at the minimum. This fixed system of reckoning is in contrast to the real events of Nuer history, which is one of human propagation inscribed in Nuer genealogical reckoning, expansion and contraction of territory, and the actual bifurcation and amalgamation of lineage segments. But the Nuer fit such events into a structure of lineages with a time depth of 10–12 generations when there is no reason to presume that they have existed for so short a time.

The Nuer express their political history as a fixed structure of relations between lineage segments. They prefer a stylization of history to a record of the endless march of unique events in an irreversible flow of time. The absence of writing and the strength of oral culture no doubt have something to do with it. The content of relations changes and is irreversible, no matter who the ancestors are or where a particular named unit fits into the hierarchy, but the structure remains constant. Eternal returns, with their prophecies of foretelling and fulfilment, or dynastic genealogies that record the unfolding succession of heroic deeds from some fixed starting point into a receding time horizon, are not the stuff of Nuer social history.

The Nuer are a tribal state without centralized authority. Their kin-ordering and genealogical reckoning are the key to their construction of time, which contrasts greatly with that of empires. In those states where imperial elites (military and religious) ruled over vast areas and innumerable village communities from imperial centres, there developed an awareness of time itself as an objective instrument of power and legitimation.

Time in China

Jean DeBernardi

Department of Anthropology, University of Alberta, AB, Canada

Chinese methods of calculating time are of great antiquity. According to the *Shi Ji* (Book of Records), as early as 2254 BCE, Emperor Yao employed astronomers to calculate solstices and

equinoxes and predict seasonal change so that farmers would know when to plant crops. Oracle bones dating to ca. 1200–1181 BCE attest to the fact that Shang dynasty Chinese calculated time using a 60-day divinatory calendar that still is in widespread use. The early development of methods of measuring time was not entirely endogenous to China; cultures throughout the ancient world exchanged astronomical ideas and data.

Striking similarities exist between calendrical systems in widely separated regions, including parallels between the form and names of the Chinese and Maya divinatory calendars (Whittaker, 1990). At least as early as the first century BCE, the Chinese used a lunisolar calendar resembling the standardized Babylonian calendar developed in the fourth century BCE. The similarities suggest borrowing, and it is possible that the Babylonians were the original inspiration for the Chinese luni-solar calendar. In the Sui and Tang dynasties (589–960), Indian astronomers resided in China, and during the Yuan dynasty (1280–1368) Chinese collaborated with Persian and Arab astronomers. The technology of observation and measurement included an observatory built in Beijing during the Yuan dynasty. Contrasting with the astronomical system developed in Greek and medieval European astronomy, Chinese astronomy was polar and equatorial rather than ecliptic.

Although at times the Chinese borrowed astronomical ideas and technologies, these became incorporated into a system of time reckoning rooted in Chinese society. Sociologists have observed that time is a symbolic structure that represents a society's collective rhythms. In the Chinese calendar, some elements are based on astronomical cycles, while others have been shaped by the temporal rhythms of social life.

Chinese notions of the seasonal cycle are integrated into a system of classification based on the dualism of *yang* and *yin*. While *yang* and *yin* are often defined in terms of the complementary dualism of male and female, in Chinese they originally referred to sun and shadow, the very elements used to measure the changing seasons. For Chinese metaphysicians, *yang* and *yin* came

to denote primal cosmic forces that interacted to generate a cycle of five phases (*wuxing*) which were identified with five primary elements (wood, fire, metal, water, and earth). These phases and their associated elements were in turn identified with the seasons. Thus, Chinese classified spring with wood, summer with fire, autumn with metal, and winter with water, while earth was associated with the midpoint of the year.

This model of cyclical process associated the five phases with five colors (green, red, yellow, white, and black), directions (east, south, the center, west, and north), organs of the body, tastes, planets, virtues, passions, etc. Chinese elaborated rituals designed to control this cyclical process. Throughout the yearly cycle, the emperor performed rites to inaugurate the seasons, and his performance gave concrete expression to the association of season, direction, color, and ritual. Chinese thought that by means of these ritual performances, the emperor could ensure harmony in the universe and interpreted natural calamities as evidence of his loss of the “mandate of heaven” (Granet, 1934). The cosmological framework of *yin* and *yang* and the five phases also informed Daoist alchemy and still is fundamental to the Daoist rituals of popular religious culture (DeBernardi, 1992; Schipper 1993).

Chinese philosophers and scientists appreciated the importance of natural cycles and also linked the cycles of time with the cycles of human life. Not only they did link cyclic ideas of time to the liturgical calendar that regulated rites performed in the imperial court and its temples, but also they linked it to the microcosm of the body. In contrast with the taxonomic thinking that informs much Western science, Chinese explored patterns of function *through* time to make sense of various experiences, including ones related to health and illness. The associations of the five phases applied not only to the yearly cycle but also to the cycle of the month and the day. For example, Chinese medical practitioners thought that the “seasons of the day” could predict crisis periods for physical disorders affecting different parts of the body (Farquhar, 1992).

While cyclical time had key significance, Chinese also had a well-developed concept of continuous time. This concept found expression in “continuity history writing,” in which historians sought to chronicle causal sequences of events in history. While official historians recorded the objective facts of history, they also critiqued the past in a form of “praise and blame” historiography that sought to discern the logic of a *Dao* (path or way) that had its origins in Heaven. Thus, the rulers of China employed history, like divination, as a means to gain insight into the logic of events and as a guide to appropriate action.

In an agricultural society, charting seasonal change was crucial, and one responsibility of the emperor was promulgation of the lunisolar calendar. Since promulgation of a calendar was a political responsibility and privilege, astronomy was an orthodox Confucian science. Every year a Board of Mathematicians led by an Imperial Astronomer (who was a Minister of State) prepared the calendar. After the emperor approved the new almanac, high-ranking officials received it with great ceremony. The emperor, who had exclusive rights to promulgate the calendar, also bestowed the almanac upon China’s vassal states as a mark of favor. During the Qing dynasty (1644–1911) over two million almanacs were officially printed each year, and excess copies were available for sale. Despite this imperial monopoly, pirated editions circulated widely. Rebellious feudal lords sometimes expressed their withdrawal of allegiance by issuing a new calendar.

The Chinese used the calendar as an instrument to predict not only the best time for planting but also the best time to initiate action. As a consequence, astronomy was interwoven with astrology and divination. Details of the zodiac are still published in the almanac, and the Chinese may consult this source to predict dates that are propitious or unpropitious for human undertakings such as weddings.

The most ancient method of timekeeping is the 60-day divinatory calendar, evidence for which appears on oracle bones in the late Shang dynasty (ca. 2300–1181 BCE). The cycle is composed of two interlocking sets of cyclical characters that

are combined to form 60 unique two-syllable names. The “Ten Heavenly Stems” (*tian gan*) revolve in concert with the “Twelve Earthly Branches” (*di zhi*), and their combination generated 60 cyclical names. These 60 combinations were arranged in six 10-day groupings called *xun*. Since the first century BCE, years have been named after the consecutive days of the divinatory calendar, producing a repeating 60-year cycle. In the late Shang dynasty, the *xun* of the dyadic divinatory cycle was the basis for ordering sacrifices to royal ancestors. A full ritual cycle was completed in 360 days, increased to 370 by the addition of an intercalary *xun* every second cycle. This arrangement created a calendar that approximated the length of a solar year.

The Twelve Earthly Branches correspond to the 12 signs of the Chinese solar zodiac, which also name 12 constellations used to calculate the position of the sun every month. The zodiac animals (six wild or mythical and six domestic) are the rat, ox, tiger, rabbit, dragon, snake, horse, sheep, monkey, cock, dog, and pig. They are divided between passive *yin* and active *yang* symbols and name the years in a repeating 12-year cycle. Chinese popular wisdom has it that persons who are born in a particular year have personalities shaped by the associated zodiac animal. Individuals should avoid marriage with persons born in the zodiac years of antagonistic animals and also seek to avoid having children during such years (Smith, 1991).

The task facing early astronomers who sought to invent a calendar for use in predicting the seasons involved reconciling lunar and solar cycles. The regular cycle of the moon provided a readily observed celestial clock, but the lunar year does not correspond with the seasons, since 12 lunar months produces a cycle of only 354 days. The yearly cycle of the sun produces a cycle of 365 1/4 days, but it does not predict the full moon. The 365-day Gregorian calendar follows the solar year alone, with an extra day added every leap year to adjust for the fraction. The Chinese, however, sought to reconcile solar and lunar calendars (Bredon and Mitrophanow, 1927: pp. 6-10).

By the eighth century BCE, Chinese could calculate and record eclipses, and they knew of the Metonic cycle. This was a 19-year cycle at whose beginning and end the sun and moon are in the same relative position to each other. Discovery of this cycle led to a system of coordination of lunar and solar cycles that resembles the Babylonian standardized calendar, and some authors have suggested that this system was perhaps borrowed rather than invented (for details of debates, see Needham, 1959, pp. 171–177).

During 19 solar years, there were 235 lunar months, and Chinese astronomers divided these into 12 years that were 12 lunar months long and 7 years that were 13 lunar months long. The 13-month years were produced by duplicating 1 month. The inventor of this calendar introduced that intercalary month in such a way as to ensure that the winter solstice always occurred in the eleventh lunar month, the summer solstice in the fifth, the spring equinox in the second, and the autumn equinox in the eighth. In addition, the introduction of an intercalary month ensured that the Chinese New Year always fell on the second new moon after the winter solstice, between January 20th and February 19th.

Before the adoption of the lunisolar calendar, Chinese dynasties inaugurated their reign by adopting a different month as the beginning of the civil year. The Manchus are said to have followed this tradition when Emperor Kang Xi in 1669 adopted the revised calendar proposed to him by the Jesuit Father Verbiest. The Republican Government expressed its break with imperial rule by adopting the Gregorian calendar, which was favored because of its universality. Its adoption also eliminated a powerful source of imperial authority, since monopolistic control of the calendar contributed to a mystification of Manchu power. Nonetheless, the traditional lunisolar almanac still regulates the cycle of community festivals and the rituals of ancestor worship.

Time in Islam

M. S. Stern

Islam is now a major global religion. It has its roots, however, in the Arabian Peninsula of the early seventh century. Its core elements were implanted in the early years and all later developments relate, one way or another, to that core.

In pre-Islamic Arabia some elements seem to have related to time (*dahr*) as fate, an underlying force directing human and natural destiny. It was conceived as a power existing eternally and responsible for the happiness or agony of humanity. Thus the *Qurʾān* refers to those who “say. . . ‘nothing but time can destroy us’.” [45:24/23]

While time was generally seen as an impersonal force, some people sought to identify God with time or, worse still by Islamic standards, to use this concept to deny God’s existence. The Apostolic Tradition (*ḥadīth*) records Muḥammad’s saying that Allah commanded men not to blame *dahr* “for I [God] am *dahr*.” Later there were various groups of radical thinkers, often only vaguely defined and known primarily from polemic references, who asserted “the eternity of the course of time.” Accordingly, because they denied both Creation and Judgment, the beginning and end of time, they were considered atheists. The term *dahrīya*, therefore, came to encompass a broad spectrum of dissenters advocating some form of atheism and/or hedonistic materialism.

Islam universally views time as created. It is God’s handiwork which, like all Creation, is under God’s command. God acts in and through history but, being eternal, time does not encompass him. Nature is also his Creation but, while it manifests his greatness, it in no way encompasses Allah.

According to al-Bayḍāwī (d. 1282) in the *Anwār at-tanzīl wa-asrār at-taʾwīl* (The Lights of the Revelation and the Secrets of the Interpretation), time consists of *mudda*, the period of revolution of the sphere from beginning to end (i.e., the totality of time); *az-Zamān*, a gross subdivision of *mudda* into long periods of time (e.g., specific historical eras such as dynastic reigns); and *al-Waqt*, a fine subdivision of *zamān* into definite points of time or short intervals (e.g., precise times of the five obligatory prayers).

There are some within the Islamic tradition who assert that time, begun at Creation, has no necessary end. Al-Ghazālī (1058–1111), speaking in the *Tahāfut al-falāsifah* (Inconsistency of the Philosophers) for the mainstream tradition,

teaches that religious dogma, for example the Day of Judgment, points to a finite end to time.

Measurement of Time

The two most significant historical eras, in the consciousness of Muslims, are the Age of Ignorance (*al-Jāhiliya*), the Dark Age in Arabia before the revelation of the *Qurʾān*, and the Islamic age stretching from the formation of the Islamic community in AD 622 until the end of history at Judgment.

There is evidence which suggests that most ancient Arabs followed a pure lunar calendar. About two centuries before the Prophet, apparently under the influence of Jewish civilization, many in Arabia adopted a lunisolar calendar. After Muḥammad’s transfer to Medina (the *hijra*), an absolute lunar calculation was mandated.

The *hijrī* year consists, in theory, of 12 months of 29 days, 12 h, 44 min, and 3 s. In fact, for various practical reasons, the lunar months are computed variously as having either 29 or 30 days. The *hijrī* year is about 11 days shorter than the solar year. There is no intercalation to the solar. Any particular *hijrī* date, over a period of approximately 33 years, will move through all four solar seasons.

A number of Islamic societies have introduced a solar or lunisolar calendar (e.g., pre-revolutionary Iran, Kemalist Turkey). None of these has achieved any universal acceptance among the world’s Muslims. It is accepted, further, that such a calendar has no support in the *Qurʾān* or the prophetic *Sunnah*.

Specific points in the yearly cycle are sanctified and celebrated in various ways. There are many local holidays and celebrations, and certain times are acknowledged as primary Muslim holy times. The first is the month of Ramaḍān during which the Muḥammad’s prophetic career was begun. For the entire month Muslims abstain from food, drink, smoking, and sexual contact. The fast

begins each day at the moment that there is sufficient light to distinguish white from black threads. It ends each night after the sun has completely set. Islam's "lesser feast," *'Id al-Fiṭr* (breakfast), brings release from the month-long abstention.

The "greater feast" is the *'Id al-Aḍḥā* (Feast of Sacrifice) on the tenth of Dhū 'l-Hijjah. It celebrates the end of the Holy Pilgrimage (*Hajj*) and reenacts Abraham's sacrifice of a ram in place of his son (*Qur'ān* 37:102). The primary sacrifice is made by the pilgrims in the valley of Minā, near Mecca. Muslims all over the world also offer such a sacrifice.

In Muḥammad's time the Arabs counted a 7-day week. There is evidence that this is a relatively late practice imported from Babylonia (or, perhaps, by way of resident Jewish communities who observed the weekly Sabbath). Earlier time flow was divided according to weather and similar seasonal changes. Under Islam the week was given significance by assigning a special status to Friday. It is not a day of rest but rather a day of communal prayer.

Time as a Moral Dimension

By [the token of] Time [through the Ages].
Verily Man is in loss.
Except such as have faith and do righteous deeds
and
[join together]
in the mutual teaching of truth and of patience and
constancy. (*Qur'ān* 103: 1–3)

There are numerous Quranic references to man's time and God's time. "He rules [all] affairs from the heavens to the earth: in the end will [all affairs] go up to Him, on a Day, the space whereof will be [as] a thousand years of your reckoning [32:5]." Creation, as well, is said to have been effected in 6 days [32:4]. Exegetes often emphasize that the days of Creation, before the placement of the sun, refer to God's days reckoned as a thousand man years (and, in 70:4, to 50,000 years). Muslim scholars reiterate that Allah is in no way bound by time; he is totally transcendent.

The point is that throughout the course of human history God maintains full control over his Creation. In his mercy Allah provided man with a window to his will and commanded him in the straight path. When time ends, at Judgment, man will face his time compacted to God's scale. "... In the immense future all affairs will go up to Him, for He will be the Judge, and His restoration of all values will be as a day or an hour or the twinkling of an eye; and yet to our idea it will be a thousand years" (Yūsuf Alī).

There is an implicit ambivalence as regards the pursuit of scientific and technological knowledge. In so far as the Muslim centers his consciousness on God, his greatness and omnipotence, he can easily succumb to a fatalistic acceptance of what comes to him. He then asserts God's absolute will and denies causality in nature. Without cause and effect there is no necessary natural order. In so far as man sees time as his sphere of action, he can hear the Quranic command to perceive God in his Creation. Exploration of the world becomes an act of moral compliance.

Time's purpose is to serve as an arena of moral action. It is the place which God has established for the exercise of will. Judgment and consequent assignment to paradise or hellfire will mean the end of time, its sole purpose being the setting for man's surrender.

Time in Korea

Moon-hyon Nam

Konkuk University and Jagyeongnu Research
Institute, Seoul, South Korea

Timekeeping: Introduction

In the Confucianism-dominated ancient East Asia, following the practices of Emperors Yao and Shun became the ideal politics of royal statesmanship, which was believed to be a way to realize the rule of heaven. Therefore, “observing the heavens and granting the seasons” became a priority for all rulers. As a result, the armillary sphere, a basic instrument for celestial observation, was developed and made the calendrical system based on the observation results collected through this device. Chinese calendar, astronomical instruments and star maps, and timekeeping systems and timepieces were introduced to the Korean peninsula from remote antiquity. Timekeeping was both a royal duty and a royal prerogative in premodern Korea since the period of the Three Kingdoms (ca. 57 BC to 935 AD) of Silla, Baekje, and Goguryeo. In this period, Han and Tang Chinese-style sundials and clepsydras (water clocks) might have been introduced, although they developed fire clocks such as incense sticks at Buddhist temples. Baekje sent astronomers and calendar experts to Japan to teach calendar- and clock-making from 554 AD. It is believed that the clepsydra of Emperor Tenji (r. 661–671) deifying as God of Time in Japan was made in 671 AD by the Koreans coming across the sea. In 647, stargazing tower (*Cheomseongdae*), as its name implies, was built at Gyeongju during the Silla Queen Seondeok’s (r. 632–647) reign and has survived intact for more than 1,360 years. Actually, four different astronomical observatories have been referred to as *Cheomseongdae* in Korean historical records. The first one was located in Pyongyang, the then capital of the

Goguryeo kingdom. Unfortunately, the structure no longer remains. Another two, in Goryeo and Joseon kingdoms, still stand in the outskirts of Kaesong, North Korea, and in Seoul, South Korea. The one in Gyeongju is known as the oldest astronomical observatory in East Asia. In 718, the Silla government set up the Office of Water Clock and constructed a water clock at Hwangryong Temple, to assign doctors of astronomy and clepsydra. In 774, they cast a big bronze bell at Bongdeok-sa Temple, which tolled to announce the time for morning and evening prayers (Fig. 1).

During the Three Kingdoms period, they imported Chinese calendars, such as the “Great Expansion” calendar *Dayan-li*, “Chimer Virtue” calendar *Linte-li*, and “Extending Enlightenment” calendar *Xuanming-li* from Tang. They divided a full day into 12 double-hours and 100 marks and also divided a night into five night watches. Civilian time-announcing services were carried out according to the calendars employing water clock and bell (Nam, 1995).

The Goryeo dynasty (918–1391) kept a close relationship with the Yuan from the mid-thirteenth century and employed the “Season-Granting” calendar *Shoushi-li* distributed by the Yuan emperor in 1281 and the “Great Concordance” *Datong-li* from the Ming in 1370, respectively. These were major tools for the dual timekeeping. A full day was divided into 12 double-hours and 100 marks, a night subdivided into five night watches and 25 points. They ran the Astro-calendric Office *Seoun-gwan* which took charge of the astronomical, geographical, calendrical, and clepsydral timekeeping matters. They made water clocks and sundials (Nam, 1995). King Chungseon (r. 1298, 1308–1313) of the Goryeo collected the Neo-Confucian Song literature and the Mongolian and Islamic sciences in Yuan China and brought them to Kaesong. The al-Jazari’s (1206) book on the Islamic clock-making technology employing ball-powered transmissions might have been included in the king’s collections.

Time in Korea, Fig. 1 The Divine Bell of King Seongdeok (r. 702–737) the Great is also commonly known as the “Emille Bell,” a name related to child sacrifice legend. Some say that that bell, when struck, produces the sound of a baby crying (*em-ee-leh*). Today, taped recordings of the tolling bell have also been played on the hour to mark the time of day (Collection: Gyeongju National Museum, Gyeongju. Height: 375 cm, Weight: 19 tons. Photo by MH Nam (author), 1994)

The founders of Joseon dynasty (1392–1910) adopted Neo-Confucianism as the state ideology. The Neo-Confucian tenet of “observing the heaven and granting the seasons to the people” led to the production of calendars for farming and the reckoning of the time of day, which provided motivations to make accurate timekeepers. The Joseon rulers took over the Astro-calendric Office from the former dynasty and assigned astronomical, geographical, calendrical, meteorological, divinations, and clepsydral timekeeping duties. Ten engineers and craftsmen to make timekeepers and for timekeeping were assigned

to the Astro-calendric Office. The Prime State Councilor was appointed as the head of the office. Astronomy became the major discipline of the royal family.

The founder King Taejo (r. 1392–1398) built a bell tower *jongnu* in the downtown capital which announced the time provided by a newly cast night-watch clepsydra *gyeong-nu* in 1398. It was the first standard timekeeper in the capital Hanyang (now Seoul). The third monarch, Taejong (r. 1400–1418), was a scientifically inclined ruler who worked with his son, the future King Sejong (r. 1418–1450), to improve printing technology and clock-making. Assisting them in their works was the Court Engineer Jang Yeong-sil (ca. 1380–1445) who cast a new night-watch clepsydra *gyeongjeom-jigi*, the Striking Clepsydras, and various instruments.

After ascending the throne, Sejong commissioned his ministers to correct the calendar because of difficulties in measuring time with the Nanjing-based almanac in Seoul. Sejong decided to adjust the Season-Granting system according to the latitude 37.5°N of Seoul and saw that it required the installation of astronomical instruments and clocks to observe the heavens and to measure with accuracy the hours at Seoul.

The king began to equip the astronomical observatory from 1432 to 1438, and five astronomical installations and instruments were constructed and ten kinds of timekeeping devices were created. In the course of the project, Jang Yeong-sil invented and installed two Striking Clepsydras: the Striking Palace Clepsydra employed as standard timekeeper and the Striking Heavenly Clepsydra as an ideological instrument (see details below). In the portable water clocks, Traveling Clepsydras were carried by the Clepsydra Warden of the Astro-calendric Office for royal processions outside the royal palaces, rituals, and defenses at the military camps in the border.

The sundials mounting an equatorial-polar alignment and/or all thread-gnomons Scaphe-, Plummet-, Horizontal-, and South-determining

were new and used at the palace observatory, Astro-calendric Office, military camps, public places, and palaces. Among these, the upward-facing Scaphe sundial *Angbuilgui* was made for public use in 1434 and has been developed with various different types up to today (see details below). Two small simplified Armilla were employed to observe celestial bodies and time-keeping at the palace observatory and Astro-calendric Office, respectively. The sun-and-star time-determination instrument and its smaller version were created for measuring solar and sidereal hours. They were composed of a sun-and star-dial mounting an equatorial-polar alignment and thread gnomons. And most of these were installed on the west side of the *Gyeongbokgung* palace compound, and several instruments and timekeepers were at the Astro-calendric Office near the palace for regular observations. Calendrical undertakings ended in 1445 after more than 20 years of effort. The correction of the Season-Granting system fitted to the latitude of Seoul 37.5°N ended with the publishing of the *Calculations on the Celestial Motions of Seven Regulators Calendar Inner and Outer Volume* [*Chiljeongsan-nae-oe-pyeon*]. These provided a base for making timekeepers and keeping local time at Seoul for 200 or more years until the adoption of the Western-Style Temporal Model Calendar *Shixian-li* which was developed by the Jesuit missionaries and Chinese calendar experts of Beijing in the early seventeenth century.

In 1653, 17th monarch Hyojong (r. 1649–1659) promulgated adopting the Temporal Model Calendar. The traditional *Chiljeongsan*-based timekeeping system was changed to the Western time-reckoning system: 12 double-hours and 96 marks in a full day replacing the former 12 double-hours and 100 marks accordingly. The circumference of the circle 365 1/4 *do* (traditional Chinese degree) was changed to 360°. Several kinds of mechanical clocks were introduced through China and Japan from the 1630s. In 1669, a Court Engineer Yi Min-cheol (1631–1715) and a Professor of Astronomy Song I-yeong (1619–1692) made a traditional water-operated astronomical clock

and a Western-style astronomical clock driven by weights, respectively (see details below).

Timekeepers: Water Clocks, Mechanical Clocks, and Sundials

The Striking Palace Clepsydra

The Chief Court Engineer Jang Yeong-sil invented the Striking Palace Clepsydra *Jagyeok-gungnu* in 1433 under the order and commission of Sejong. It was installed at Announcing Clepsydra Pavilion *Borugak* in the *Gyeongbokgung* and the king assigned it as standard timekeeper from the first day of seventh lunar moon of 1434. The story on the making of the clock was written by Academicians of Hall of Worthies Kim Don (1385–1440) and Kim Jo (d. 1445) as the *Records of the Announcing Clepsydra Pavilion*. The records consist of memoirs by Kim Jo and inscriptions with preface by Kim Jo. The new clock was named after its housing as the Clock of the Announcing Clepsydra Pavilion *Borugangnu* officially or “palace clepsydra” *geumnu* literally.

According to the Kim Don’s memoirs, the Striking Palace Clepsydra consisted of three parts: (1) an inflow-type water-clock system with the dual-time-measuring and dual-time small-ball releasing mechanisms to mark the beginning of each double-hour and each night watch and their points. The system comprised three water-delivering vessels (reservoir, compensator, regulator) on the deck, an overflow receptacle, and two water-receiving vessels (time-measuring cylinders) to float indicator rods for daily changeover on the floor bed. On top of the measuring vessels, two rectangular-shaped dual-time small-ball releasing mechanisms (ball racks) are erected as shown in the left part of Fig. 2. The mechanisms cause dual-time small balls to fall, i.e., 12 balls for 12 double-hours and 25 for five night watches and their 25 points sequentially as time passes. (2) The Striking Palace Clepsydra also consisted of dual-time-announcing systems powered by dual-time large balls at the beginning of each double-hour and at each night watch and their points. The systems consisted of a dual-time

Time in Korea, Fig. 2 The Striking Palace Clepsydra. (Reconstruction) *Left*: An inflow-type water-clock system. *Right*: A dual-time-announcing system. *Middle*: Four dual-time small-ball receiving funnels and their ball transmission routes to connect the water-clock and the dual-time-announcing systems. The time-announcing mechanisms are as follows: Water trickles from the regulating vessel into a measuring vessel, to raise the indicating-rod float as time passes, to trigger the ball racks on top of the vessel, and to release the dual-time

small copper balls on the ball racks. The balls fall into the funnels on top of the vessel and travel through routes to enter to the dual-time small-ball-to-large-ball converters, to discharge hen-egg-sized iron balls to the double-hours and a night watch and their points machines under the converters. The large balls activate the machine controllers to sound the bell and to display a time tablet and to sound the drum and the gong by the corresponding figures (Length: 6 m, Height: 5.7 m, Width: 2 m. Collection of the National Palace Museum of Korea, Seoul)

small-ball-to-large-ball converter, the double-hour announcing machine, and the night watches and their points announcing machine as shown in the right part of Fig. 2. The double-hour machine consisted of a bell and a wooden striker on the pedestal and 12 time tablets (names of 12 double-hour animals) bearing wooden figures in the box which were linked to the double-hour machine controller in the box. When the bell rang at the beginning of each double-hour, then the corresponding time figure popped up to replace the former one sequentially telling the time. The night watches and their points machine consisted of a drum and a gong which are hit by wooden figures on the pedestal which were linked to the night watches and their points machine controller in the box. To announce night watches, the drum and the gong sounded for the number of night watch points. Two machine controllers were activated by hen-egg-sized large iron balls falling from the dual-time small-ball-to-large-ball converter. (3) There were four dual-time small-ball receiving funnels and their ball transmission

routes which were connected with the water-clock and the dual-time-announcing systems.

The clock was used as standard timekeeper to announce the time of the curfew alert *Injeong* (“people at rest”) in the evening and the removal of curfew *Paru* (“quit the clepsydra”) in the morning and mid-day drum *Ogo* (“quit morning services”) following the sunrise and sunset times in Seoul. The uniqueness of the clock was its capability to announce dual times automatically with visual and audible signals. The length of each night watch varies throughout a year and a night watch corresponds to about 2 h today. To match the variations of the 24 Fortnightly Periods with daily civilian life, the maker of the clock made an operating instruction *Manual on the Calculation and Usage of Clepsydra Indicator-rods Nuju-tongui* according to the sunrise and sunset hours of Seoul employing the *Calculations on the Celestial Motions of Seven Regulators* calendar *Inner Volume*. And then they calibrated night watch graduations with the double-hours on the water-clock’s float rods and made 11 pairs of

the indicating rods and the ball racks for sequential use throughout a year. The clepsydra warden began with the first pair of an indicating rod and a ball rack at the winter solstice and changed the pairs until the summer solstice (11th pair) sequentially at about 15 day intervals and then vice versa, from the 11th pair to the second one before the winter solstice. They used first and eleventh pairs for about 30 days each (Nam, 2014).

In 1536, under the commission of King Jungjong (r. 1506–1544), a court horologist, Park Se-ryong, made a copy of the Striking Palace Clepsydra of Sejong at *Changdeokgung* palace. The Sejong's Striking Palace Clepsydra was burnt down during the Japanese Hideyoshi's invasion of Korea in 1592. Fortunately, King Jungjong's 1536 clepsydra survived with some damages and it was restored in 1618 by Prince Gwanghae (r. 1609–1622) and housed at a new location in *Changgyeonggung* palace. It was used as the standard timekeeper and revived to the newly built clepsydra house on King Sejong's old *Borugak* site at *Gyeongbokgung* palace in 1863 and employed as standard timekeeper until 1895. Since then it was displayed outdoors for exhibition from 1908 and has been housed at *Deoksugung* palace since 1938 (Fig. 3) (Nam, 2000).

The Striking Palace Clepsydra is an integration of the traditional East-Asian inflow-float rod clepsydra and the Islamic ball-operated water clock (Needham et al. 1986). As we have seen above, the inflow-type water clock to measure dual time and the two ball-operated time-announcing machines to tell dual time were combined via a dual-time small-ball releasing mechanism on top of the measuring vessel, i.e., analogue to digital converter (A/DC) in a modern sense. King Sejong and his court scholars might have adopted the three-step inflow water-clock model of Wang Pu (AD 1135) of the Song dynasty in designing their water clock. And they got the ideas from the ball mechanisms of the Byzantine era and Islamic horology in designing discrete time-telling mechanisms (Hill, 1981). Early thirteen-century Islamic Engineer Al-Jazari's ball-operated Candle and Elephant

Time in Korea, Fig. 3 Remains of the 1536 replica of Sejong's 1434 Striking Palace Clepsydra are currently on the grounds of the *Deoksugung* palace. From the top, the water-delivering vessels (a reservoir, a compensator, and a regulator) are on the square-stone bases (mis-arrayed), and two dragon-ornamented inflow-float time-measuring vessels (2 m high, 32 cm in diameter, all bronze cast) are on the floor bed. In addition to the vessels, two turtle-shaped floats (copper plate machined) and an indicator rod are kept in the inflow vessels (Photo by the author MH Nam, 1994)

Clocks inspired them in designing the dual-time A/DC mechanisms and time-announcing machines (Al-Jazari, 1206; Needham et al., 1986). These innovative twofold power source methods enabled and secured accurate time measurement and effective time telling. Needham et al. (1986) argued that the transmission of ball-powered techniques of Islamic world came through China to Korea as follows:

The fact that in the fifteenth century automatically sounding clepsydias employing falling balls were in use across the entire span of the Old World, from Fez to Seoul, testifies eloquently to the ability of

ideas to travel far and quickly among the great civilisations of premodern times.

In 1437, Chief Court Engineer Jang Yeong-sil applied his experiences to make a functional astronomical clock the Striking Heavenly Clepsydra. He employed water-operated wheel mechanisms and ball mechanisms. The tradition of employing ball mechanisms was inherited by court engineers in making astronomical clocks in the seventeenth-century Korea (Nam, 2012).

The Striking Heavenly Clepsydra

In 1438, Chief Court Engineer Jang Yeong-sil completed his second Striking Clepsydra under the guidance of Sejong and installed it at the Respectful Veneration Pavilion *Heumgyeonggak* in *Gyeongbokgung* palace. So the clock was officially named the Clock of the Respectful Veneration Pavilion *Heumgyeonggang-nu*. According to the *Memoir of Respectful Veneration Pavilion Heumgyeonggak-gi*, written by the academician

Kim Don, they installed a sounding clock, a water-operated mechanical wheel, and a prime mover capable of revolving the golden model sun around a pasted-paper mountain once every day. In conjunction with the wheel, the ball mechanisms operated three kinds time-announcing mechanisms. In addition to these mechanisms, an inclining vessel was filled by overflowing water from the clepsydra. It was emptied when it was full and upright when it was half full. The mountain was surrounded by rural scenes of the four seasons depicting the farmers in rice fields. Figure 4 shows a visual image of the clock following Kim Don's memoirs.

The uniqueness of the clepsydra was its capability to demonstrate celestial movements and to announce the 12 double-hours and five night watches and their points automatically with visual and audible signals. As its name implies, it was used in conjunction with edifying Confucianism rather than observation. Kim Don said, "Everything was more ingenious and excellent

Time in Korea, Fig. 4 Artist's concept of the Striking Heavenly Clepsydra. A golden sun-model rotates along the peaks of a mountain that was surrounded by five-colored clouds once each day. Inside the pasted-paper mountain, a water-operated mechanical wheel which rotates by the trickling water which is supplied from the jade clepsydra. The wheel mechanisms are connected to the sun revolving device and three kinds of time-announcing mechanisms: (1) the Four Guardian Spirits (Eastern Blue Dragon, Southern Red Bird, Western White Tiger, and Northern Black Snake) and four female

jade time-announcing figures; (2) the 12 Spirit Generals [figures] of the Zodiac, occupying their respective positions, and 12 time tablet-bearing female jade figures on the level ground; and (3) at the southern foot of the mountain stands a high platform and four hour-jacks and bell, drum, and gong which are operated by ball mechanisms. South of the mountain stands an official figure who pours water into an inclining vessel. Around the mountain, there is rural scenery of the four seasons cited from the *Ode of Bin* depicting peasants working around the rice field, and there are wooden carvings of men, birds, and plants

than the traditional designs. All of these operations are performed automatically, without any human help. It seemed that the immortals operated the mechanisms; onlookers were struck with admiration and could not guess how it worked” (Annals of Sejong, 1438). This clock was an edifying instrument of royal prestige emphasizing the importance of observing the heavens and acknowledging the seasons and of helping agriculture and being aware of the Confucian moral tenet for all the people.

The clock was reconstructed twice in 1554 and 1614 after its destruction by fire. The last version was abolished in 1656. The clock had been maintained for 218 years, and the technical details might have been handed down and innovated upon to make subsequent astronomical clocks two decades later. Information related to design following astronomical clocks made it possible to conjecture plausible technical features (Hahn, Nam, Lee, & Lee, 2000). Detailed operational structures were not fully realized because of the dearth of technical information in the memoirs. In spite of this, the clock has its predecessors: the water-powered armillary sphere and globe tower of Su Song and Han Gong-lian in AD 1092 during the Northern Song, the Lantern Clepsydra of Guo Shoujing in 1272, the Palace Clepsydra of Yuan Shun-di during 1350s, and the Striking Palace Clepsydra, back to the al-Jazari’s Islamic water clocks. The clock inherited the East-Asian tradition of astronomical clock-making and became a forerunner of astronomical clocks of Yi Min-cheol and Song I-yeong in 1669 (Nam, 2012).

The Astronomical Clocks

Two decades after the abolishment of the Striking Heavenly Clepsydra in 1656, a magistrate, Choe Yu-ji (1603–1673), made a water-powered armillary sphere *seongi-okhyeong* in 1657. In 1664, King Hyeonjong (r. 1660–1674) ordered Yi Min-cheol and Song I-yeong to renovate Choe’s armillary sphere. In 1669, Song Jun-gil (1606–1672) submitted a petition to Hyeonjong to revive the Hall of Respectful Veneration of the Sejong. This caused Yi Min-cheol and Song

I-yeong to recreate the Striking Heavenly Clepsydra. Yi made a water-operated striking armillary sphere *honcheonui* employing a water wheel driving mechanism, an armillary sphere combined with model sun- and moon-carrying mechanisms, and a ball-operated carousel-wheel time-announcing mechanism (Annals of Hyeonjong, 1669, 17: 35ab; Hahn & Nam, 1997). It was installed by the side of the king’s chair as a symbol of kingship and then moved to Jejeong Pavilion in Changdeokgung palace after repairs in 1687.

Song I-yeong made a weight-driven striking armillary sphere called “self-sounding clock” *jamyeong-jong* employing Western clockwork. According to Kim Seok-ju’s (1634–1684) memoir, “The armillary sphere made by Song I-yeong was much same as that of Yi Min-cheol in general design, but he used the gear wheels of Western clockwork...” Both clocks employed a traditional armillary sphere with different driving methods: one was operated by a water-powered clepsydral mechanism and the other by weight-driven gear wheels, but both employed jackwork carousel wheels after the Striking Clepsydras. The jackwork figures were reduced in size and replaced by a disk time tablet and they added a ball-run mechanism incorporating a paddle wheel (Kim, 1907). It had been installed at the Office of Study Promotion and Special Advisors *Hongmungwan* until the fall of the Joseon dynasty. It was repaired under the order of King Sukjong (r. 1674–1720) by Yi Jin, and Choe Seok-jeong (1646–1715) and Oh Do-il (1645–1703) wrote *Inscriptions with Preface of Self-sounding Clock* in 1687 (Hahn & Nam, 1997). In the course of repair, Yi Jin might have adopted Christian a Huygens’ (1629–95) crown-wheel escapement and pendulum-type clockwork mechanism which was a state-of-the-art technology at that time. A small terrestrial globe showing a world map was incorporated instead of the telescopic mechanism of the armillary sphere.

Figure 5 shows the remains of Song I-yeong’s clock, showing a demonstrational armillary sphere on the left stand, two weight-drive clockworks inside the long rectangular case, and a time-announcing mechanism inside the right.

Time in Korea, Fig. 5 Outside view of Song I-yeong's astronomical clock. The armillary sphere incorporating a terrestrial globe is on the stand at left; the clockwork mechanism consisting of a striking train and two weights is inside the *long rectangular* space. The time-announcing

mechanism consisting of a moving train and the striking-release mechanism are inside the case at right. Case dimensions: 120 cm long, 98 cm high, and 52 cm wide (Photo courtesy: Korea University Museum, Seoul, Korea)

This clock was collected by Kim Sung-su (1891–1955, second vice-president of the Republic of Korea during 1950–1951) and introduced to the Western hemisphere (Jeon, 1963; Needham et al., 1986, pp. 115–152; Rufus & Lee, 1936). Needham stated, “The Song I-yeong/Yi Min-cheol clock deserves widespread recognition as a landmark in the history of East Asian horology” (Needham, 1986, p. 152). In addition, the clocks were the final versions of the Korean water-operated and weight-driven armillary sphere and the Striking Clepsydras of Sejong.

Scaphe Sundials

On the 2nd day of tenth lunar moon of the 16th year (1434) of Sejong's reign, two hemispherical concave sundials were set up in front of the Benevolent Government Bridge *hejeong-gyo* and on the southern side of the Royal Ancestral Shrine *Jongmyo* in downtown Seoul (Annals of Sejong, 61). These were the first public time-pieces in Korea, which were made of bronze in the shape of a kettle. This was a typical Korean Scaphe sundial called *Angbuilgui*. The name

came from the shape of the kettle directing toward the sky, which originated from the upward-facing instrument *yang i* of Guo Shoujing (1231–1316) of Yuan. A circular pole-pointing gnomon incorporated at the South Pole axis toward the North Pole and graduated with a reticular scale – 12 longitudinal hour-circle lines and 13 latitudinal solar-declination lines – was inside the semicircular hemisphere. To recognize common time, half of 12 of the double-hour Guardians of the Zodiac – Rabbit, Dragon, Snake, Horse, Sheep, Monkey, Rooster, and Dog – were drawn on the hour-circle lines with corresponding names of the animals as shown in Fig. 6a. Names of the 24 Fortnightly Seasons were inscribed on the 13 latitudinal solar-declination lines to know the seasons.

The pole-pointing gnomon axis is coplanar with the hour circles, and the planes of the solar-declination parallels are perpendicular to that axis. Thus, hour circles and the solar-declination parallels are perpendicular to each other. When the sun rose, the gnomon shadow indicated the Rabbit double-hour *myosi* and moved along to the hour circle via noon and to the Horse double-hour *osi* toward sunset and the

Time in Korea, Fig. 6 (a) The Scaphe sundial of King Sejong. Reconstructed by MH Nam (author), 1996, and collected by the Museum of Konkuk University, Seoul. (b) Remains of the eighteenth-century revivals of Sejong's Scaphe sundial. Collection of the National Palace Museum of Korea, Seoul (Photo: MH Nam, 1997). (c) The Scaphe sundial on its granite stand (Height:

136 cm) (Photo: MH Nam, 1995, *Deoksugung* palace, Seoul). (d) Portable Scaphe sundial made of ivory in 1873 by Kang Geon. Collection of the Seoul Museum of History. Length 6.5 cm; height 1.7 cm; width 4.2 cm (Photo: MH Nam, 2009). (e) A stamp with a Scaphe sundial (양부일구)

Rooster double-hour *yusi* in a day. At the winter solstice, the gnomon indicates a top solar-declination parallel and moves with the sun along the hour circles toward sunset the Rooster double-hours in a day. The shadow of gnomon moves downward following the seasonal change toward the summer solstice parallel and upward after the summer solstice toward the winter solstice; thus 1 year passed. When people read the shadow of the tip of the gnomon, they easily knew the present time of the day and the seasons, either.

As shown in Fig. 6b, Scaphe sundials were held up by four dragon columns standing on the

cross water grooves for orienting and leveling. On the lip were inscribed the directions corresponding to the 12 double-hours. Most of the Scaphe sundials of Sejong's reign were burnt down during the Japanese Hideyoshi's invasion in 1592 and restored at *Changdeokgung* palace in 1688 by King Sukjong (r. 1674–1720). Most of the extant Scaphe sundials were made early in the eighteenth century since the measuring of the latitude of Seoul as $37^{\circ} 39' 15''$.

The sundials were set up in front of major buildings in palaces such as the Council Hall *Sajeongjeon* where the king conducted daily affairs in *Gyeongbokgung*, the Queen's

Residence *Daejojeon*, and the Royal Library *Juhapnu* in *Changdeokgung*. Figure 6c shows the sundial on the beautifully sculptured granite sundial stand in front of the Imperial Residence in *Deoksugung* palace in Seoul.

The Scaphe sundials were made of ceramic, marble, and ivory in various types and sizes until the early twentieth century and the royal court sent several ivory or marble portable ones to Qing's court as gifts similar to those shown in Fig. 6d. Figure 6e shows a stamp with a Scaphe sundial which was issued to commemorate the 1988 Seoul Olympic Games by the Department of Post and Communication, Korea.

Hemispherical sundials were made and used for long time in the West, and in their usual form, only the solstices and equinoxes can be seen. And the gnomon was inserted on top of the hemisphere rather than the bottom in Sejong's Scaphe sundial. Korean Scaphe sundials were innovative and a conspicuous tribute to the public-spirited beneficence of the ruler (Needham et al., 1986, p. 81).

Supplementary Material

Korean Horary Systems

In ancient times, East Asians subdivided a calendar day into 12 equal intervals or "double-hours" (*si*, 時) and divided the day into 100 marks (*gak*, 刻), each mark equivalent to 14.4 min on a modern watch to tell the time at night using water clocks. Each double-hour was divided into a Beginning Half (*cho*, 初) and a Standard Half (*Jeong*, 正), and each length is 1 hour, the same as the modern hour, called "single hours." Each double-hour contained $8\frac{1}{3}$ marks of these intervals and each half-double-hour contained $4\frac{1}{6}$ marks. Before employing the Temporal Model Calendar (*Shixian-li* 時憲曆) by Qing, 12 double-hours and 100 marks timing system prevailed which was then changed to 12 double-hours and 96 marks, each mark equivalent to 15 min modern system.

The names of the 12 double-hours came from the names of 12 animals of the zodiac and read: Rat (*ja*, 子, 23–01 modern hour), Ox (*chuk*, 丑,

01–03), Tiger (*in*, 寅, 03–05), Rabbit (*myo*, 卯, 05–07), Dragon (*jin*, 辰, 07–09), Snake (*sa*, 巳, 09–11), Horse (*o*, 午, 11–13), Sheep (*mi*, 未, 13–15), Monkey (*sin*, 申, 15–17), Rooster (*yu*, 酉, 17–19), Dog (*sul*, 戌, 19–21), and Pig (*hae*, 亥, 21–23). Double-hours ran from 23 (子初) and the day began at midnight 00 (子正) half a double-hour later, not 23.

In the Season-Granting system (*Shou-shih li* 授時曆), a night is divided into five night watches which are five equal divisions of the duration divided from dusk (2.5 marks after the sunset) to dawn (2.5 marks before the sunrise). In Korea, the night watches were called *gyeong* (更) and each night watch is further subdivided into 5 points *jeom* (點).

Time in Maya Culture

Henry J. Rutz

Classic Maya culture developed from the second to the tenth centuries AD and expanded to encompass all of the Yucatan peninsula including the modern countries of Guatemala, Belize, and portions of El Salvador and Honduras. Unlike the

Aztec and Inca states, which developed highly centralized imperial cities, the Maya developed city-states. Elites intermarried, formed alliances, and shared a complex calendar.

While all empires have created multiple times to connect village community to imperial center, and earthly city to heavenly city, the historian Nancy Farriss has noted that “from their earliest recorded history, the Maya displayed an intense interest, bordering on obsession, in measuring and recording the passage of time.” Anthony Aveni (1989) observes, “The first bits of information in any Maya inscription are about time. What sets the Maya apart is not the number of time units they devised, or even their complexity; rather, it is their preoccupation with ‘commensurateness’ – perfecting the way time cycles interlock or fit together.” Over a millennium since the climax of classic Maya culture and five centuries after the Spanish conquest, Maya continue to practice their own time, albeit in modified form.

The Maya had a military state with a literate elite. Our information about their multiplicity of time comes from their own writings. Although Maya hieroglyphic writing died out, Maya elites were able to maintain an unbroken continuity from their system of writing to that of Spanish script. The language survived in many colonial documents from the sixteenth century on. Today two million people still speak more than a dozen dialects of the Mayan language.

The Maya calendar is the centerpiece of Maya concepts of time and its measurement. It consists of the conjunction of cycles upon cycles of time of long duration. Like the Gregorian calendar we use today, the Maya calendrical system was the culmination of many different cultural influences over millennia. The conception of time underlying the calendar is one of movement. Maya referred to time as a flow and perceived a need for both human and divine intervention in maintaining it. In Maya culture, people actively construct their sense of time, a point to which I return below with reference to daykeepers and their role in the regulation of everyday life.

The flow of time is incorporated into an all-encompassing cyclical pattern. Conjunction of complex forces mark cycles of different duration. The Body Count of 20 is the basic unit of Mesoamerican counting (10 fingers plus 10 toes). The classic Maya week consists of 20 named days, each propitious or unpropitious for particular activities. The 20-day week was combined with a separate series of 13 numbered days to create the Sacred Round of 260 days. Later, a Solar Year was calculated consisting of 18 20-day months plus 5 days. The solar year was articulated with the sacred round to create the Calendar Round of 52 years. The Maya also developed a Katun Round consisting of 13 20-year periods for a duration of 260 years. Despite an obsession with commensurability that led Maya priests into astronomy and cosmology, not all the cycles were articulated with each other. Late in the political development of pre-Conquest Maya culture a ► [Long Count](#) of five millennia appeared. Today, Maya daykeepers reckon the rhythms of everyday life by interpreting the solar and divinatory calendars.

Although Maya viewed time as a flow, it is also time with a content. Each day was named after a god and was qualitatively different from every other. Furthermore, the content of time was regulated by a conjunction of forces. Those days that were at the conjunction of different cycles had a greater force than other days. The larger the cycle, the greater the number of forces intermeshing from different subcycles. The Maya depicted time on stone carvings or drawings as weighty numbers carried by gods.

Intermeshing cycles produce a succession of days whose events are linear, unique, and irreversible. But this apparent linearity is an illusion because “no matter how unique a pattern of events may seem, no matter how long the sequence, it will eventually be repeated, when the governing forces of all the cycles of different dimensions coincide in one huge cycle” (Farriss, 1987).

Why these cycles? Maya observers were not disinterested observers of the heavens. Cosmic time links common people to rulers through the latters’ association with the cosmos.

The construction of cycles appears to be associated with the problems of legitimacy and political order. Returning to the same point, at least logically, is the ultimate form of reassurance against the reality of present conflict, chaos, and events that seem to be getting out of hand. As Farriss says, “Accounts of the famine in the books of Chilam Balam show less concern with starvation than with the fact that people flee into the forest to eat roots and other wild food . . . In other words, people cease to live in their customary fashion. . . Political conflicts are condemned because they disrupt the established hierarchy, and upstarts and invaders are vilified for breaking the rules.” Encompassing cycles provide a cosmic charter of legitimacy of a magnitude rarely conceived in the history of cultures.

The predictable order of cosmic time reckoning, unfortunately, depended upon human agency for execution. “It is unlikely that the Maya priests claimed to comprehend all the possible combinations of divine forces governing the subordinate movements of so immense a projection.” Past, present, and future are written in a single bound book, but one that admits of many interpretations.

How did the dual conception of cyclical and linear time work out in practice? Both serve as charters for sociopolitical arrangements, but each in its own way. It appears that classic Maya elites confined linear concepts to relatively short term duration out of choice (they possessed the literary or numeracy skills to create historical memory). Among the most important were the katun round and the chronicles written by members of Maya royal lineages during the colonial period.

The katun round, consisting of a recurring wheel (time is often depicted as a wheel in Maya stone carvings) of 13 20-year counts for a total of 260 years, recorded the important events of royal lineages. The interesting aspect of the katun round is its duality of both history and prophecy. Each year has its own name together with characteristic and appropriate events. The future is contained in the past, and therefore Maya could look to a record of the past as a guide to the future. The same pattern of events for a given year recurs every 260 years. In Chilam

Balam texts, logically associated events always occur in the same katun regardless of their inner chronology. It is as if all invasions were taken out of their chronological sequence and placed in their cosmological reckoning. Even references to the most recent “descent” – the Spanish conquest – are woven into the pre-Hispanic mix.

In addition to general reference to recurrent patterns of events there is also remarkable specificity to katun accounts, which name specific people and places, details of real famines, invasions, migrations, exiles, and rivalries. The specific content is about unique and irreversible events. The chronicles appeal to secular principles as the basis for claims to legitimacy, for example descent from previous rulers. The 20-year katun cycle may have served as a calendar for rotation and succession of ruling families in post-Classic Maya. In contrast, books of Chilam Balam that record cycles stress quality of time – joy, misery, abundance, and the place of cosmic and divine forces in their production. The sacred personages of the calendar rounds merge with their worldly actors.

There is some evidence that the Maya calendar evolved toward a dominance of linear over cyclical concepts of time during the post-Classic period as a consequence of the emergence of dynastic rule and its dominance over the more autonomous city-states of the Classic period. Unlike the calendrical system of cycles and their conjunction, which have no particular starting date, the ► [Long Count](#) system measured elapsed time from a starting point that would extend to a time horizon of 5,200 years before its repetition. This new calendar represented a radical shift from the dominance of cyclical time over linear time because its duration was long enough to encompass the ancient Calendar Round of 52 years and more recent katun round of 260 years. Specific details of human affairs accompany the Long Count and a new emphasis on written genealogies supports the hypothesis of a shift to dynastic rule.

If it is unlikely that ancient Maya priests could comprehend all the divine forces converging on particular days or years, how much less likely is it that ordinary people could use the Maya calendar

to take control of their own lives? A partial answer appears in the guise of Maya daykeepers. Barbara Tedlock (1982) has given us an account of time among Quiche Maya in the town of Momostenango, highland Guatemala. There daykeepers use an integrated solar year and the sacred round to divine whether a day is good or bad for particular activities. The appropriate determination of qualities to a day are specific to a particular client and require active participation on the part of both daykeeper and client.

Daykeepers use a set of practices referred to as “the speaking of the day” and “the speaking of the blood.” The qualities of the 20 name days are based on stipulated but vague mnemonic phrases that require interpretation by the daykeeper. Other factors specific to a client enter the picture, including the client’s character, part of which is determined by the particular day on which a child is born.

The daykeeper achieves understanding by sortilege or divination by lots. She or he mixes, grabs, and arranges piles of seeds and crystals into a pattern, all the while counting and interpreting the 260 days of the divinatory calendar. The blood is considered to be an active substance that sends signals or “speaks” to the daykeeper. The rapport between daykeeper and client is also thought to affect the divining of a day as good or bad for a particular activity. Clients come to a chosen daykeeper with a specific question about such probable occurrences as illness, accident, land disputes, building houses, inheritance, business transactions, travel, marriage, adultery, quarrels, dreams, births, deaths, and interpretation of omens. The divination is performed for the specific question posed by a particular client.

Time in Native North America

Michael Zeilik

The Pueblo people of the United States Southwest believe in a cosmos in which nature functions with the active cooperation of humankind. The proper ceremonies must be carried out at the proper time so that the cosmic order is sustained. Traditional doctrines held that there were correct times for planting, harvesting, hunting, ceremonies, and many other activities – all embedded in a sense of sacred time. The right times for these crucial undertakings are established by astronomical observations to regulate the ritual calendar. The cycles of the sun and moon set the rhythm of Pueblo time.

Sacred time is ordered with different levels of periodicities. The longest appears to be the seasonal year. We have very little evidence – almost all ambiguous – that the Pueblos kept long counts or tallies greater than a year. Until the twentieth century, with the intrusion of European concepts of time, no indigenous interest appears in tracking cycles over many years. The yearly cycle is all important; after its end, a new, equally unique one begins. Within the seasonal span, ceremonies occur in a fixed sequence, in which the completion of one sets the stage for the next. The observation of the phases of the moon marked the subdivision of the year. Within a night, the start and end of some ceremonies are flagged by observations of the positions of certain stars, especially the Pleiades as seen from the

smokehole of a *kiva*, a structure used as a ceremonial room.

The shortest unit of time reckoned by the Pueblos is the day, which begins with sunrise. The day has vague subdivisions into loose “hours,” most of which are noted near sunrise and sunset by the color of the sky. About the only time of day noticed with any care is that of noon, which is typically observed by the length and directions of shadows cast by the edges of walls, buildings, trees, or sticks embedded in the ground.

A religious official has the responsibility and the authority to set the ceremonial dates within the ritual cycle. The crucial task entrusted to this official is the forecasting of the correct date by making anticipatory astronomical observations. The dates are announced ahead of time so that the people of the pueblo can enter into proper preparations (abstinence, practicing songs and dances, preparing costumes and special foods) so that the ceremony may be carried out with “good heart” and be effective.

Typically, one official – the Sun Priest – performs the sun-watching for the seasonal cycle, which includes the planting schedule. He does so from a sun-watching station that is usually located within or close to the pueblo. From this fixed spot, the Sun Priest keeps a horizon calendar (usually at sunrise using an observation of the first gleam) against the horizon profile. He knows from experience that when the sun rises (or sets) against a certain horizon feature, so many days will elapse until, say, the winter solstice. Then he uses tally markers (such as a knotted cord) to count down to that day, with an announcement made to the pueblo a few days ahead of the celebratory date. This anticipatory technique allows the Sun Priests to forecast the dates of the solstices to within 1 day of the astronomically correct date when the sun appears to “stand still” at its sunrise point. The observations made about 2 weeks in advance catch the sun when the angular speed of its sunrise position is large enough to be discerned by the naked eye on a day-to-day basis. Hence, this practice neatly solves both a cultural and astronomical problem.

Moon watching regulates timings between the seasonal and daily ones. The official responsible for tracking the phases of the moon generally is not the one who watches the sun. A Pueblo month begins with the observation of the first visible crescent and ends with the last. The days of invisibility are not typically counted. Calendar sticks were used to tally the observed months.

The months of the year are counted starting with the first before the winter solstice ceremony. The first five (or six) are named (usually after seasonal characteristics); then these names are repeated for the next five or six. The lunar calendar needs to be synchronized with the solar one, which is accomplished by adding an intercalary month (which can be as short as 4 days!) at the end of the regular count or after the winter solstice.

Although Pueblo people feared eclipses of the sun and the moon, they had no way to forecast them. In part, this lack was related to their disinterest in keeping counts longer than a year. We also find no evidence for knowledge of the 18.6-year lunar standstill cycle, even though the moon certainly was observed rising and setting. The historic Pueblo culture did not seem to attach any importance to this astronomical cycle so it was ignored.

The ancestors of the Pueblo people were the Anasazi, who inhabited what is now the greater Four Corners area of the US Southwest as a settled agricultural people. During the height of the classic Anasazi culture some thousand years ago, two major sites developed: Mesa Verde and Chaco Canyon. A regional center developed in the San Juan basin around Chaco by AD 1110; as many as 70 communities dispersed among 50,000 km² were integrated into a socioeconomic and ritual network connected by a road system.

How did the Anasazi regulate and track time? By using ethnographic analogy, we can generate hypotheses about Anasazi astronomy that can be checked against the archaeological record. The most important cycle of time for the Pueblos is the seasonal year, which is typically tracked by horizon calendars. Anticipatory observations are made about 2 weeks prior to the solstices. Of the

Anasazi sites field-tested so far, about one-third have reasonable horizon calendars.

A secondary strategy employed in the historic Pueblos used a special opening or window to cast sunlight on an opposing wall. The best Anasazi analogs to this type of interior observational technique occur in Hovenweep National Monument at Hovenweep Castle, Unit Type House, and the Cajon Group ruins with small portals. Hovenweep Castle and Cajon ruins work at sunset, Unit Type House just after sunrise. In all three locations, the horizon profiles lack the relief for tracking horizon calendars. For all, the throw from the shadow-casting edges is large enough so that the linear motion on the receiving wall is typically a few centimeters per day from the sun's angular positional change at sunrise or sunset. The evidence so far hints that interior light and shadow casting played an important role in Anasazi seasonal time keeping.

Exterior light and shadow casting was not an important time keeping technique in historic times. It may have been used more extensively by the Anasazi though perhaps more for ritual than calendric purposes. The three-slab site atop Fajada Butte in Chaco Canyon has been much investigated; so has the Holly site at Hovenweep. In both these cases, light and shadow cast by rock edges fall onto panels of rock art at important seasonal times of the year. These exterior sites generally suffer from a lack of resolving power for reliable calendric forecasting, if we apply the standard achieved by the historic Pueblo Sun Priests – within a day of the astronomical date of the solstices. Hence, these sites may have served as sun shrines for offerings to the sun with a light and shadow display that served a commemorative rather than a calendric function.

We have no firm evidence so far of prehistoric monthly lunar calendars, though such a count of days would have a unique sequence tied to the phases of the moon. No rock art in the Anasazi region has been demonstrated to display the measure of a lunar tally.

Occasional claims have been made that the Anasazi noted the 18.6-year standstill cycle of the moon. The hypothesis of attention to this interval has been put forth for the Fajada three-slab site and for Chimney Rock Archaeological

Area in Colorado (among a few others). The most convincing case is made for Chimney Rock, where the natural rock pillars (after which the site is named) act as a natural foresight when viewed from the site of Chimney Rock Pueblo, a Chacoan outlier, which was occupied from about 1075 to 1175.

The orientation allows a spectacular anticipation and forecasting of the major lunar standstills. For about two and a half years prior to the standstill, the moon rises between the pillars for 1 or 2 days per month. Starting after the summer solstice, the moon appears as a waxing crescent. Finally, near the winter solstice, the full moon stands between the pillars at around sunset. Hence, the priest in charge of the moon watching could forecast the date of the standstill and also the full moon nearest the winter solstice – an important conjunction among the historic Pueblos.

Time: Non-Western Views

Time is a difficult notion, since time beliefs underlie a variety of seemingly unrelated areas like (1) scientific theory, (2) philosophy of

science, (3) religious beliefs about the nature of life after death, and consequently about the soul (4) human values and the (5) nature of language and logic, etc. These various time beliefs may or may not cohere with each other.

The structure of the English language, unlike that of the Hopi (American Indian) language, presupposes that time and space are entirely separate entities, and this makes it hard to understand the intermingling of time and space in relativity theory. As another example, the Buddhist Dhamma (ethics, way of life) is closely connected to the Buddha's concept of *paticca samuppāda*, or conditioned coorigination, the proper understanding of which requires the concept of a structured time, in which the instants of time are not featureless geometrical points. This notion of a structured time is incompatible with the two-valued logic assumed in Western philosophical discourse. In Buddhist thought, seemingly contradictory properties may coexist, as in the quantum-mechanical Schrödinger's cat who is both alive and dead at a single instant of time. Thus, the attempt to understand one aspect of a non-Western view of time, such as the Buddhist notion of *paticca samuppāda*, can force us to reconsider fundamental issues like the logic underlying Western thought.

Any attempt to provide an account of non-Western views of time is a very difficult enterprise, involving complex relationships across widely different areas of knowledge, and potential conflicts at a deep level with stock metaphysical assumptions underlying even the language and logic of Western discourse. This entire gamut of relationships between different pictures of time has been covered in the books *Time: Towards a Consistent Theory*, and *The Eleven Pictures of Time*, by this author, but it is too complex to be covered in the span of this one article, which will focus on only a single aspect related to the Western stereotype of non-Western beliefs about time.

The Western Stereotype: "Linear" Time Versus "Cyclic" Time

Non-Western views of time have typically been represented in Western literature and scholarship

by contrasting Western “linear” time with non-Western “cyclic” time. Linear time is endowed with a variety of positive properties: rationality, progress, free will, etc. while cyclic time is attached to a variety of negative properties: spirituality, stasis, fatalism.

The first step needed to understand non-Western views of time is to get rid of this stereotype.

For example, the time beliefs underlying scientific theory are not the same as those underlying the philosophy of science, and the two do not cohere, but both can be classified as linear time. Thus, scientific theory is today presented in the form of differential equations, such as Newton’s laws of motion, or the Hilbert-Einstein equations, or Schrödinger’s equation. These equations fix the state of the cosmos at any time, once its initial state is known. However, all these equations involve the mathematical notion of a derivative with respect to time – for example, velocity, or the rate of change of position, is the time derivative of position, and acceleration is the rate of change of velocity or the time derivative of velocity. On the existing Western mathematical understanding of the calculus, these derivatives with respect to time force us to suppose that time is a continuum, which can be represented using real numbers. That is, current scientific theory necessarily presupposes that time is like the real line, or that time is “superlinear”.

On the other hand, our reasons for believing in this or that scientific theory are (or ought to be) based on experiments, and this presupposes the belief that one can perform various experiments, the outcomes of which were not all determined beforehand, by the state of the cosmos at some moment in the remote past. That is, the philosophy of science presupposes a different belief about time: that the future of the cosmos is a consequence of human choices and actions, and not merely of its past state. One does not normally stop to think about such presuppositions because everyday human actions are premised on the same belief that human actions are powerless to change the past (“no use crying over spilt milk”) but that they do bring about the future in some small way (“if I don’t watch the milk it will

boil over”). Thus, the philosophy of science subscribes to the belief in “mundane time”.

These two types of time, superlinear and mundane, are both linear, but they are nevertheless incompatible and in conflict with each other. This conflict is a serious matter, for it pits scientific theory against the reasons for regarding it as valid. How is this conflict to be resolved? This would naturally seem to require a correction in one or the other picture of time.

However, the slightest alteration in one’s time beliefs can have profound consequences. Changing the picture of time in scientific theory fundamentally changes the type of equations used to formulate the models of physics. On the other hand, if one were to believe that the future of the cosmos has already been rigidly determined by its past, there would be little point to human action, and life itself would become meaningless, as in the theory of the Stoics, or in Nietzsche’s thought.

Since there are different notions of linear time, such as superlinear time and mundane time, which do not cohere with each other, so the very category of linear time is not meaningful. The category of cyclic time is not meaningful for similar reasons.

On the other hand, there need not be any particular conflict between a locally superlinear time and a globally recurrent cosmos. If the cosmos is restricted to a finite region, like a gas in a box, and evolves deterministically – according to Newtonian mechanics, say – then the Poincaré recurrence theorem tells us that, with probability one every state of the cosmos must repeat to an arbitrary degree of precision, infinitely often. Recurrence would similarly take place even if the cosmos evolves probabilistically rather than deterministically, so long as the future state of the cosmos depends only on its present state, an assumption more precisely formulated in current mathematics as the Markovian assumption for the evolution of a stochastic process. These recurrence theorems assure us that a recurrent cosmos, instead of being in conflict with superlinear time, is a logical consequence of it, under some rather general conditions, such as finiteness. In the above situations of cosmic recurrence, it could

be argued that time only seems superlinear because the time scale of cyclicity – the recurrence time – may be very large, just as the earth seems flat, although it is round, since it is very large. Thus, a linear picture of time, need not be in conflict with a cyclic picture of time.

This meaningless dichotomy of linear versus cyclic time has nevertheless been persistently used in the West to characterize non-Western thought about time. A non-Western historical perspective on the development of Western time beliefs is helpful in understanding the origins of this incorrect (but widespread) stereotype about time and its linkage to religious ideology.

Quasi-Cyclic Time and the Soul

Early notions of the soul (in India, for example) were based on the belief that the cosmos went through recurrent cycles, or, equivalently, that time was quasi-cyclic. It was believed that each cycle of the cosmos lasted for an enormous duration of time – billions of years – and that each cycle of the cosmos was approximately like the preceding one. Events repeated in approximately similar ways in successive cycles of the cosmos. Roughly the same people were reborn in successive cycles of the cosmos, and lived roughly the same lives, and died roughly the same death repeatedly, across cosmic cycles. This perceived state of affairs was described by saying that each individual has a soul, which persisted beyond death, and was repeatedly reborn (in successive cycles of the cosmos), until such time as it achieved deliverance.

The duration of a cycle of the cosmos is reckoned in the *Viṣṇu Purāṇa* as a day and night of Brahma, and amounted to 8.64 billion years. (An ordinary day and night amount to 86,400 s.)

This notion of a soul which persists across vast cosmic cycles is not a metaphysical notion, since it presupposes a cosmic state of affairs, which may or may not be the case. That is, this notion of the soul is a physical notion, since it involves a refutable or falsifiable picture of the cosmos.

It is a common error to confound quasi-cyclic time with eternal recurrence. It was not generally believed that these cosmic cycles were exact or eternal. The whole possibility of deliverance – *mokṣa*, *nirvāṇa* – was premised on the idea that these cycles were neither exact nor eternal. (However, the category of cyclic time encourages such an error by suggesting that various types of cyclic time are the same.)

In India, this was the traditional view of time and life after death held from before the time of the Buddha. The Lokāyata denied the belief in life after death as a fraud. An interesting feature of this denial is how Pāyāsi sought to establish the non-existence of the soul by performing some 37 experiments with dying men, and condemned felons. It is unlikely that such experiments were ever performed anywhere else.

The Buddhists did not deny this cosmic state of affairs. Indeed, popular stories like the *Jātaka* tales clearly accepted what was then the prevalent common belief about the world. What Buddhists denied was only the significance of cosmic recurrence, for they denied the existence of a soul or any continuity between two similar individuals across two cycles of the cosmos. In fact, they also denied that anything essential persisted between two similar individuals across even two instants of time: they maintained that the seed in the granary is a distinct entity from the seed in the ground, which is bloated. The seed in the granary cannot be the cause of a plant, because the seed in the granary remains a seed at the next instant. There is a similarity between the two seeds, and hence, due to the paucity of names, one gives the same name to both seeds. Therefore, in the Buddhist view it would not be proper to say that there is some essential sameness in an individual which persists from birth to death: in the Buddhist view, an individual exists (unchanged) only for a single instant.

This notion of quasi-cyclic time is incorporated in artistic or mythical representations, like the Wheel of Time, the Phoenix, or the Plumed Serpent of Central America, that are found from across the world, and certainly existed in Egypt. And, as Herodotus informs us, numerous ideas, customs, and religious beliefs were transmitted

from the Egyptians to the early Greeks. Therefore, it is not surprising that a similar notion of the soul is found in the works of Plato, and was subsequently developed by the Alexandrian Neoplatonic philosophers.

Indeed, it is little known that this belief in quasi-cyclic time was the anchor of early Christianity, as enunciated by one of its greatest real (as opposed to mythical) teachers, Origen of Alexandria (third to fourth century CE). This early Christian notion of cyclic time was remarkably similar to what is today known as the Hindu doctrine of *karma-samskāra*. According to this doctrine, the actions (*karma*) in one cycle determine the dispositions (*samskāra*) in the next cycle, and the objective of life is taken to be deliverance (*mokṣa*) from these repeated births and deaths.

Quasi-Cyclic Time, Immanence and Equity

Curiously, while cyclic time and *karma-samskāra* are today associated with casteism and inequity, in early Christianity, Origen argued in his *De Principis* that this notion demonstrated both equity and justice: equity, since God had created all souls equal, and justice, since souls were rewarded and punished in each cycle of the cosmos according to the merits or demerits they had earned from their good or bad actions in the preceding cycle. Origen's argument was not an isolated curiosity.

Thus, the notion of equity was related to immanence or the idea of divinity within man, and hence the importance of deep introspection. The discipline of Yoga (union) is not a physical exercise, but a technique of meditation or introspection to bring about the union of ātman with Brahman, inside man, and thence lead to deliverance. Mathematics (geometry) was perceived by early Greeks to be a technique, exactly like Yoga, to achieve the same goal. Thus, in Plato's *Meno*, Socrates demonstrated the slave boy's prior knowledge of mathematics, in support of his theory that all learning was but reminiscence of the prior knowledge of the soul. Likewise, Proclus

explained the etymology of mathematics (from *mathesis* or learning) as the science of learning, or the science of the soul, since he thought mathematics related to eternal truths, and forced one into an introspective state, which then aroused the immortal soul and induced it to recollect its past knowledge, which it had forgotten since birth.

Immanence related to equity, since all souls were regarded as being part of one God. This relation is well brought out by the following story. Śāṅkara was the founder of Advaita Vedānta, a philosophical system which asserts that ātman and Brahman are "not two" (but one). Śāṅkara was returning from his bath in the river, when he was accosted by a *candāla* (outcaste). By force of habit, Śāṅkara shrank back. After this the *candāla* taunted him, asking how Śāṅkara could maintain this distinction when both had an ātman one with Brahman, hence equal to each other. Realizing his mistake, Śāṅkara prostrated himself before the *candāla*. Almost every theorem of Euclid's *Elements* is about equality (not congruence), and this was unambiguously related to political equality as in the mystery story that there is "no royal road to geometry". The connection to political equality was made quite explicit in subsequent Islamic rational theology (*aql-i-kalam*). The lasting impact this had on Islam is obvious from the fact that religious-minded emperors like Aurangzeb, even though they ruled vast empires, worked to earn their livelihood – something observed with great astonishment by Europeans who had never known any ruler of this sort. In the early Christian version, Origen argued that not only were all souls created equal, but they would again become equal at the end of time, since all would ultimately achieve deliverance, as in *karma-samskāra*, and there would be a time when God would be all in all.

This notion of an immanent God was also essentially a celebration of the creativity of life. Man creates the future cosmos (at least a tiny part of it), just because God is in Man (and also other living creatures). All people are equal, just because all people are equally parts of one God. Since these notions involved a celebration of

creativity, they were associated with what have been called “fertility cults”, such as the worship of Bacchus or Dionysius. In India, various Tantric schools have many similar practices. The relation of equity to creativity is well brought out by the Lokayata festival, today known as Holi. On the one hand it is related to the harvest and is thus a celebration of creativity. The custom of throwing color on people was intended to erase the social distinctions that are displayed by means of clothes, and in fact to erase all individuality. The custom of taking bhang (marijuana) was intended to further creativity by heightening sexual passion.

Inequity as the Basis of Linear Time

After Constantine, this belief in the equity of all souls stood in the way of the political goals of the church, which now viewed the world from the imperial perspective of the Roman state: if all souls would be saved anyway what was the advantage to be gained by turning Christian? If God was within man, where was the need to fear God, and be obedient to the priest? Hence, theologians like Augustine proposed to erase equity and erect a transcendent God who would judge people and establish a simplistic moral division between good (Christians) and bad (non-Christians). In the revised picture proposed by state Christianity, all souls were NOT equal, so not all souls were eventually saved. Instead God established a permanent inequity in the world, sending some souls (those of good Christians) to heaven (forever), and other souls (non-Christians) to hell, as described in gory detail by Dante, for example. Reincarnation was accordingly changed to resurrection – life after death, just once.

Because the earlier notion of soul depended upon a view of life after death deriving from the belief in quasi-cyclic time, time beliefs were also compelled to change with this changed notion of the soul and of life after death. Time beliefs changed from quasi-cyclic time to linear apocalyptic time: the world, as conceived by Augustine, began a few thousand years ago, and would

soon come to an end. The notion of the soul became metaphysical.

Thus, the question of linear versus cyclic time is an issue that lies at the very foundation of Christianity (and the related historical notion of the West, as in Toynbee’s classification, used more recently by Huntington). Rejection of that view of (apocalyptic) linear time would amount to a denial of the entire religious ideology of state Christianity, as it is understood today. This explains the significance and importance to the West of the competitive stereotype of linear time versus cyclic, directed as much against early Christianity as it is directed against non-Western views of time.

The Western Misrepresentation of Quasi-Cyclic Time as Supercyclic

Augustine argued against Origen’s view, by misrepresenting “cyclic” time as eternal recurrence or a state of affairs where deliverance was available to none. He asserted that the cosmos would recur exactly, so that even Jesus Christ would be repeatedly reborn and repeatedly crucified, so that no one could be saved. “Heaven forbid that we believe this, for Christ having died once for our sins, rising again, dies no more”. Augustine then rejected this state of affairs on the grounds of “fatalism” (which, he quibbled, was different from “determinism”).

This was certainly a misrepresentation of non-Western views, where deliverance from the cycle of birth-death-rebirth was not only held to be possible, it was regarded as the ultimate aim of life. This was also a misrepresentation of Origen who explicitly stated:

And now I do not understand by what proofs they can maintain their position, who assert that worlds sometimes come into existence which are...in all respects equal. For...then it will come to pass that Adam and Eve will do the same things which they did before: there will be a second time the same deluge... So therefore it seems to me...that a diversity of worlds may exist with changes of no unimportant kind...in that age [world] which preceded this, Christ did not suffer... (*De Principis*, Book II, chapter III.4-5)

Augustine's misrepresentation of "cyclic" time may be presented thus: time was thought to be quasi-cyclic, whether in *karma-samskāra* or in Origen's teachings; however, Augustine misrepresented quasi-cyclic time as supercyclic time – a situation (of "eternal and exact recurrence") where no change is possible in the cosmos, which repeats mindlessly like a stuck record (this "repetition" being in some implicitly assumed notion of increasing time, external to the cosmos, perhaps in the mind of God). Most Western thinkers have fallen into the same Augustinian trap of confounding "cyclic" time with "eternal recurrence" because they lacked even the words required to make a distinction between different varieties of cyclic time.

Therefore, Augustine's misrepresentation of Origen's notion of "cyclic" time has confused a long line of Western thinkers like Nietzsche, who founded an entire philosophy on this misunderstanding of "cyclic" time as supercyclic time or "eternal recurrence of the same". The same confusion between quasi-cyclic time and eternal recurrence can be found in T. S. Eliot, or in Mircea Eliade's *The Myth of the Eternal Return*.

Starting from Newton, the same confusion about "cyclic" time persists in scientific theory to this day. For example, Stephen Hawking and G. F. R. Ellis, in their *Large Scale Structure of Spacetime*, argue against closed time loops (a third variety of partially cyclic time, distinct from quasi-cyclic time and super-cyclic time) repeating exactly Augustine's mistaken arguments. The first step of the argument confounds any sort of cyclicity with eternal recurrence, and the second step rejects eternal recurrence on grounds of fatalism. More recently, arguments in the scientific literature related to the Grandfather paradox of time travel, which involves a loop in time, have again endlessly repeated Augustine's wrong arguments. The confusion between quasi-cyclic time and eternal recurrence seems to reverberate eternally in Western thought: "cyclic" time represents "eternal recurrence" hence fatalism, and should be rejected. On the contrary, as this author has pointed out, such closed loops in time, being causally inexplicable from the past, are the way to have spontaneity, or

creativity, within the frame of current physical theory.

Thus, the Western stereotype of non-Western views of time involves a very deep-seated and long-standing confusion about the nature of time within Western thought, starting from Augustine and stretching down to people like Newton, Einstein, and Hawking.

There are a few other aspects of non-Western views of time that deserve at least a brief mention.

Discrete Versus Continuous Time

First, consider the issue of discrete versus continuous time. The belief that time is a continuum is forced in present-day physics, as we have seen, only by the Western understanding of the calculus, based on an idealistic understanding of mathematics. However, the calculus that developed in India incorporated a different understanding of mathematics, that could be called a realistic understanding. The difference between the two may be explained with reference to the Buddhist denial of the existence of the soul. The Buddhists (especially followers of Nāgārjuna's *śūnyavāda*) maintain that between two instants of time, an individual changes, and there is nothing "essential" in the individual that remains the same. In common parlance, and for practical purposes, we neglect or zero the differences as inconsequential, or non-representable, due to a paucity of names.

Let us now apply this understanding to a number like π , which denotes the ratio of the circumference of a circle to its diameter. No matter how we try to express this number, it cannot be specified – that would require a supertask. In idealistic (formal) mathematics, it is asserted that there really is such a number, although any actual representation of it will always only be approximate or erroneous. In realistic mathematics it would be asserted that calculations can only be done with an actual representation and not an idealized one. There is a paucity of names, and therefore we use a representation appropriate for a given practical purpose, zeroing certain things

treated as non-representable. The subtle difference between the two positions is brought out very clearly in the representation of such numbers on a computer; the actual numbers (floating point numbers) do not follow the same rules or “laws”, such as the associative law for addition that the ideal “real” numbers are supposed to obey.

This leads to a fundamentally different understanding of “infinitesimals” (as non-representable quantities discarded in a calculation), which presented such a problem for Newton and Leibniz. However, all practical conclusions drawn from the calculus use realistic mathematics and computation, rather than idealistic mathematics. Therefore, the idealistic point of view, which forces time to be a continuum in physics, involves the superposition of “extra baggage” from Western metaphysics, and there is no real need to believe that: time may well be regarded as discrete or atomic, provided one does the calculus with a different philosophy of mathematics. The point here is not to argue that time is, in fact, discrete, but rather that the discreteness or continuity of time should not be fixed purely from mathematical and metaphysical considerations, since these metaphysical considerations could be fundamentally different in the non-West.

Atomically Structured Time and Quasi Truth-Functional Logic

The second question concerns the link between time beliefs and logic. Time may be related to logic through Wittgenstein’s notion of logical worlds: the state of the physical world at an instant of time can be specified by specifying all the statements that are true at that instant of time. In the West it has been believed that if A is true at an instant of time, then its negation $\sim A$ cannot be true at that very instant. Certainly there are schools of thought in the non-West which also subscribe to this belief, but it is not universal. Buddhist and Jaina logics permit both A and $\sim A$ to be true at an instant of time. This involves the concept of an atomically structured time. The classical way to explain this would be to think of an instant of time as a microcosm. A modern

explanation for this state of affairs can be provided using microphysical loops in time.

Imagine that one has a time machine, and that one puts Schrödinger’s cat (now dead) on board the time machine and sends it back to the time of Schrödinger. The events here described from a future perspective would actually have been observed by Schrödinger somewhat differently: for Schrödinger, the “observed” sequence of events would have been that time spontaneously and inexplicably split into two streams (both part of this world), in one of which the cat is alive, and in the other it is dead. (At the microphysical level, one can actually “see” a somewhat analogous phenomenon of a photon or a particle of light splitting into an electron-positron pair, which may later recombine to produce back a photon. The positron has exactly the properties of an electron travelling back in time, so the process can also be described as an electron executing a closed circuit in time.) These two streams of time, witnessed (or rather inferred) by Schrödinger, are NOT “parallel” worlds, for the two worlds do meet, and the two cats would coalesce back into a single cat at the time we put the cat into the time machine.

In place of imaginary time machines, one can construct a more realistic desktop model involving parallel computing, although understanding this requires a little more technical knowledge. In parallel computing, a single process executing on parallel processors may be in multiple states at a “single instant” of time. Needless to say, “parallel” is a bit of a misnomer, since it is an essential feature of parallel computing that the processors (logical worlds, in the Wittgensteinian sense) and processes communicate with each other, and that they branch and collapse. Time, so to say, acquires a structure, and it is necessary to take into account this structure to understand the semantics of formal parallel computing languages.

Microphysical closed time loops enable us to understand how an atom of time can nevertheless have a structure, in the sense that multiple logical worlds are attached to a single instant of time. This structure is manifested not by further subdivision of the atomic instant, but by a change of logic. In such a situation of an atomically structured time, it is perfectly possible to have both

A and not-A valid at a single instant of time that cannot be further decomposed.

This notion of an atomically structured time or a structured instant is the basic unit of reality in Buddhism. It leads to the alternative notion of “causality” in Buddhism, called *paticca samuppāda*, or “conditioned co-origination”. The present is not the cause of the future, but the future cooriginates, conditioned by the past. *Paticca samuppāda* is identified by the Buddha as the key to his Dhamma. Thus, the use of a logic of four alternatives in Buddhism is not incidental to Buddhism but is integrally linked to its worldview, for it is only through an understanding of the causes of *dukkha* that one can remove it.

Ontically Broken Time

The common terminology of the laws of physics – for example, Newton’s laws of motion – is related to the theological idea that creation was a one-time process and that subsequent states of the cosmos were controlled by God using laws. This idea of a clockwork cosmos is denied in many non-Western systems of thought. Al-Ghazālī, argued from a different perspective, where the world is continuously created by God. In this situation, any causal connection becomes a restraint on the powers of God; al-Ghazālī denied the existence of causal connections. He conceded that there are observed regularities in the cosmos, but he explained them as arising from force of habit. God habitually creates smoke with fire; he is not obliged to do so. Of course, one does not know on what time scale God changes habits, but it could be imagined that the cosmos is such that not only would physical theories change, but physics itself would change, over a time scale of, say, a thousand years.

More to the point, this helps us to see the historical evolution of the idea of the laws of God. Thus, al-Ghazālī was speaking about an immanent God, the apparent restrictions on whose powers were all too obvious. When this was taken over in the West, as by John Scotus Duns, it created a problem, because it was supposed (at least by the opponents of this point of

view) that this description concerned a transcendent God. Under those circumstances, God would become a terrible tyrant, since one would never know what to expect next. Accordingly, God’s intervention was toned down, and his role limited to instituting laws. This led eventually to superlinear time.

²Okinawa Study Center, The Open University of Japan, Okinawa, Japan

Tofuyo, fermented tofu (soybean curd) made by the complicated actions of *Monascus*,

Aspergillus, and *Bacillus*, is a traditional fermented tofu in Okinawa, Japan. Fermented tofu has been widely consumed in East and Southeast Asian countries for a long time. Its origin has been considered to be *red-sufu*, which is a traditional fermented tofu of mainland China and Taiwan, and it was brought to Okinawa from Fujian, China, during the period of the Ryukyu dynasty in the eighteenth century. In Japan, fermented tofu, *red-sufu*, has been called *nyufu* (*rufu*) or *funyu* (*furu*) (Ohta, 1965a, b).

Chinese *sufu* is prepared by overgrowing with a mold of *Actinomucor*, *Mucor*, or *Rhizopus* on the surface of tofu, and it is further fermented in a mixture of salt brine and rice wine (Han, Rombouts, & Nout, 2001; Su, 1986; Wang & Hesseltine, 1970). Although there are several kinds of commercial products of *sufu* in Taiwan (Fig. 1), *red-sufu* is colored with red mold rice (*red koji* or *beni koji*), which is prepared by growing the mold of *Monascus anka* or *Monascus purpureus* on cooked rice. For the variation of *sufu* products, other additives are frequently added into the brine solution, imparting either additional color or flavor to the various types of *sufu* (Wang & Hesseltine).

Red-sufu was brined and had a strong taste. At first, it was unpalatable to the Okinawan people (Yasuda, 1983). Hence the process of making it was improved so it became a refined tofuyo, by using awamori, which is a traditional distilled liquor, in place of using a large amount of salt. Tofuyo prepared by the improved method became an indigenous fermented tofu product of Okinawa with a mild flavor and low salt. In addition, it is highly nutritious with high-quality protein, fat, carbohydrates, and other nutrients. Therefore, it is both a low-salt and low-cholesterol cheese-like vegetable product.

During the Ryukyu dynasty, the Royal family and high society relished tofuyo as both a health and gourmet food; however, it was hardly known to commoners (Yasuda, 1983). Tofuyo has some beneficial properties such as the smooth cheese-like texture, being a valuable source of protein, and improving blood circulation. Thus, they took delight in eating it not only as a nutritious side dish but also as a health food. Traditionally,

Tofuyo in Japan, Fig. 1 Commercial products of *sifu* (*furu*) made in Taiwan

Tofuyo in Japan, Fig. 2 Tofuyo and awamori

tofuyo has been directly consumed as a dish eaten with awamori or as cakes served at teatime for ladies (Fig. 2).

At that time, the techniques of making tofuyo were handed on to the next generation among only a few people in high society until the end of World War II (Yasuda, 1983). Thus, awareness and production techniques were very limited

even in Okinawa. In order to develop the tofuyo manufacturing industry, we have investigated the features of its production and scientifically analyzed its characteristics (Yasuda, 1990). Although the scientific aspects of tofuyo have yet to be fully clarified, the outcomes have already been transferred to the local industry in Okinawa, and the market for tofuyo is now developing in Japan and other Asian countries. Recently, it has received a lot of attention as a health food, which has physiological activities derived from soybean and fungal metabolites (Kuba-Miyara & Yasuda, 2012; Yasuda, Tachibana, & Kuba-Miyara, 2012).

History of Tofuyo

Consuming traditional tofu in East and Southeast Asian countries is known as *toufu-ru*, *toufu-ju*, *furu*, *rufu*, *sufu*, *fuyu*, *tou-yu*, and *tau-zu* in mainland China and Taiwan, *tafuri* in The Philippines, *tau ju* in Malaysia, *tau-fu yee* in Thailand, and *chao* or *dau-phu-nyu* in Vietnam (Han et al., 2001; Shurtleff & Aoyagi, 1979). Interestingly, fermented tofu, known as tofuyo, has never been

found in the mainland of Japan and Korea. The history of tofuyo has been reported in Japanese (Yasuda, 1983) and also in the special report on the history of traditional fermented soybean foods written by Shurtleff & Aoyagi in English (Shurtleff & Aoyagi, 2007).

History of Fermented Tofu

The origin of tofuyo is believed to be *sufu*, which is the traditional fermented tofu of China and Taiwan, and its beginnings have been considered to be in mainland China (Katsura, 1996; Yasuda, 1983). However, the exact dates and location of this origin remain obscure. The first description concerning fermented tofu is found in the book *Peng Long Ye Hua* written by Li Rihua in the Ming dynasty (1368–1644). Fermented tofu is also described in *Pen Ts'ao Kang Mu* (*Honzo Kou Moku* in Japanese), which is a famous book on Chinese medicinal plants written by Li Shih-Chen in 1596. Interestingly, the preparation techniques of fermented tofu described in both books are different; the former was prepared with molded tofu, and the latter did not use the molding process. The term *rufu* also appears in the section on animals in this book, but it is not fermented tofu. In this case, it refers to milk curd (yogurt), which is produced from the coagulation of protein in milk under acidic conditions.

Coming to the Ch'ing dynasty (1644–1912), some records concerning the production of fermented tofu appear, indicating that the molding process became mainstream for *rufu* production. The molding procedure for fermented tofu is described in the book *Shi Xian Hong Mi* written by Zhu Yizun in 1644. In this record, there is an interesting notation that the fermented tofu was made with *red koji*, which is called *red mold rice*. This description is one part of the evidence that the origin of tofuyo derived from *rufu* (*sufu*). The guidebook on local production in China, *Jiang Nan Tong Zhi* written by Huang Zhijun in 1737, introduced *rufu* as one of the finest products in the district of Jiang Nan, China. In this guidebook, *rufu* was not animal milk curd but fermented soybean curd. The manufacturing procedure of

the fermented tofu recorded in *Xing Yuan Lu* written by Li Shi-Ting in the mid-Qianlong period (1757–1776) is hardly different from the modern methods. Moreover, the details of fermented tofu, *rufu*, regarding the white type, famous production sites, and other aspects were also described in *Sui Yuan Shi Dan* written by Yuan Mei (1782). From these descriptions, it can be concluded that development and spread of fermented tofu originated in the Ch'ing dynasty and became popular in the diets of people in mainland China and Taiwan. Fermented tofu established in China spread to neighboring countries in East and Southeast Asia, and it was given individual names in each country. One of them, *tofuyo*, which is Okinawa traditional fermented soybean food, was traditionally made in the home or in small cottage industries until recently.

Geographic Location and Special Features of Okinawa

Tofuyo has a long and interesting history in Okinawa prefecture of Japan, and it has been passed down for a long period of nearly 200 years (Yasuda, 2011). There is no record that the tofuyo-like product was consumed in mainland Japan in the past; it is part of the distinctive history and location of Okinawa.

Okinawa is located at the most southern prefecture in Japan and is formed as an arch by a few hundred islands of the Ryukyu narrow islands extending from southwest Kyushu in Japan to Taiwan over a 1,000 km distance (Fig. 3). In the fifteenth century, the Ryukyu Kingdom (1429–1872) was established in Okinawa. The Kingdom thrived as a trading nation connecting with Japan, China, and Southeast Asian countries. The Ryukyu Kingdom existed until the Japanese Meiji government (1872) officially annexed it.

History of Tofuyo in Okinawa

The first description of fermented tofu products in mainland Japan is in the book *Tofu Hyaku Chin*

Tofuyo in Japan,
Fig. 3 Locality of
 Okinawa, Japan

Zokuhen (The Sequel to One Hundred Favorite Tofu Recipes) written by Ka Hitsu Jun in 1783. In this book, he gives instructions for how to make *red tofu* and *toufu-ji*. However, this description was similar to that of Chinese-style *red sufu*, also known as *red furu*, rather than that of *tofuyo*. Thus, it is thought that these fermented tofu products are more different than might first be surmised with *tofuyo* in Okinawa. Unfortunately, these fermented products have subsequently disappeared and can no longer be found in mainland Japan.

On the other hand, the Ryukyu Kingdom at the time maintained close commercial relations with mainland China, and that fact is formally recorded in the Ryukyu's Old Language Dictionary, *Kongo Kensyu*, in 1711 or in the book on the history of Ryukyu, *Ryukyu Koku Yurai Ki*, in 1713 edited by the Government of Ryukyu Ohfu (Royal Residence). Thus, it was believed that *sufu* and its production methods were brought to Okinawa from China (probably from Fujian, China) with the cultural exchanges. *Red sufu*

was likely introduced to the Ryukyu Kingdom during the late 1700s. However, even in these records, there is little detailed information regarding the fermented tofu, *red tofu*, *rufu*, *furu*, or *tofu-ru*. The brined product of *red sufu* had a strong taste and smell. For this reason, it was unpalatable for the people at that time and was recreated to suit their palate by using *awamori*. Thereafter, they were able to decrease the amount of salt in the original recipe and increase the shelf life without salt. In this way, the traditional *tofuyo* with an elegant, mellow, and delicious fermented soybean food was newly established.

At the present moment, the earliest known indirect reference regarding fermented tofu is found in the book *Account of a Voyage of Discovery to the West Corea and the Great Loo-Choo Island* written by Basil Hall in 1818. Hall and his party visited a Naha port on the way from China in 1816 and received a reception along with local cuisine and entertainment from the Government of Ryukyu Kingdom. In this

book, they described what happened at the reception. They ate something like cheese, and it is considered that the cheese-like food mentioned may be tofuyo.

Direct reference to tofuyo is found in *Gozen Hon Sou* written by Tokashiki Tsukan Pechin, who was a physician and high-ranking officer of the Ryukyu Kingdom in 1832. In this book, he introduced tofuyo, and according to his description, it was supposed to be delicious in flavor and have a favorable influence on the stomach. Moreover, as judged from the customs at the time, it was considered that tofuyo was consumed by the royal family and the upper classes as a side dish or a medicinal food in Okinawa. However, in fact, there was no reference to any record from 1832 until 1938 since it was a carefully guarded family secret.

From the early Showa era (after 1926) in Japan, preparation of homemade tofuyo began to be popular among the upper classes in Okinawa. However, its preparation method was not clarified at all. It is recorded that ladies ate it with tea and men took it with awamori. Typically, small tofuyo cubes were placed on a small dish and eaten with chopsticks or a toothpick. Even at that time, tofuyo was never widely consumed by regular people because it was only rarely made at home. In 1938, Baron Sho Jun, who was a descendant of the Ryukyu Royal Family and a well-known connoisseur of good food, wrote an article entitled “In Praise of Tofu” in the magazine *Monthly Ryukyu*. In this article, he said that tofuyo was one of the best rare and tasty foods in the world if not the best.

After World War II (after 1945), the technique of making tofuyo was passed on, and consequently, tofuyo came to be known to the common people. With the expansion of awareness of tofuyo, its industrialization came to be desired. However, in order to make tofuyo industrially, we were required to clarify features of tofuyo making that depend upon intuition and experience. To solve these matters, we revealed its features scientifically and then established the basic technology involved in tofuyo manufacturing (Yasuda, 1990). We transferred the outcomes obtained along the way to the local industry

during the 1980s. Subsequently, tofuyo, which reflects the food culture at the time of the Ryukyu dynasty, has been marketed. Nowadays, much attention has been paid to tofuyo as a health food that is both cholesterol free and low salt.

Making of Tofuyo

The manufacturing method of traditional tofuyo consists of three major parts: preparing tofu (soybean curd) and dehydrated tofu cubes, making koji, and soaking and ripening. A flowchart for tofuyo making is shown in Fig. 4.

Processes for Making Tofu and Dehydrated Tofu Cubes

To prepare tofu, soybeans were first washed, soaked in tap water overnight, and then ground together with water. The mixture was heated and strained through a coarse cloth to separate the soymilk from the insoluble residues referred to as okara. The soymilk was then heated, and a coagulant was added into the heating soymilk to coagulate the soy protein. The coagulated soymilk was then transferred to a mold of a cloth-lined wooden box and pressed with a weight so as to remove the whey. Tofu appropriate for making tofuyo has to be hard, and its texture affects the quality of the product. The product has a suitable elasticity and fine texture during fermentation (Yasuda & Hokama, 1984).

For preparation of dehydrated tofu, the tofu prepared above was cut into 2 cm cubes, and the cubes were dehydrated for from 24 to 48 h. Since microorganisms such as bacteria grow on the surface of tofu cubes, their surfaces were washed with awamori (Yasuda et al., 1992). The resulting dehydrated tofu cubes were immersed in moromi, which is fermented broth prepared with koji, awamori, and salt. If the dehydrated tofu cubes were too soft, they would become mush during the ripening period. In contrast, if the cubes were too hard, it would be difficult to get a favorable texture.

Tofuyo in Japan,

Fig. 4 Process for making tofuyo

To establish a suitable texture of the tofu cubes for making tofuyo, we prepared different-hardness tofu cubes according to some dehydration methods and investigated their hardness values. We confirmed that the tofuyo prepared with tofu cubes dehydrated by mechanical methods such as by warm wind, in the oven, or under vacuum were not palatable and did not progress in the ripening. Therefore, the best quality of tofuyo was obtained with tofu cubes that were gradually dehydrated at room temperature (Yasuda & Hokama, 1984).

Some bacteria can grow on the surface of tofu cubes during dehydration. Some might produce high proteolytic and lipolytic activities due to its nutritional attribute. It suggests that the bacteria grown on the surface of tofu cubes may play an important role in “prefermentation,” which may affect the quality of tofuyo products. In fact, *Bacillus pumilus* TYO-67, which was isolated from the surface of tofu cubes during dehydration, produced abundant high secretory proteinase activity. In this research, we confirmed that the protein content of tofu cubes inoculated with

the bacterium during dehydration was lower than that of those uninoculated (Yasuda et al., 1992). In addition, we demonstrated that the inoculation of *B. pumilus* TYO-67 to the dehydrated tofu cubes shows faster maturation of tofuyo than that of uninoculation. Therefore, it was scientifically shown that the microorganisms grown on the surface of dehydrated tofu cubes may play an important role in “prefermentation” (Yasuda, 2003; Yasuda et al., 1992; Yasuda, Aoyama, Sakaguchi, Nakachi, & Kobamoto, 1999).

Processes for Making Koji

Koji, mold rice, is an important material for fermentation of tofuyo (Miyazato, 1977; Yasuda, Uechi, & Miyazato, 1981, 1983). For making rice koji, polished nonglutinous rice is used because it is essential that the mycelia of fungus quickly penetrate the rice kernel. Polished rice is soaked in water overnight, and the unabsorbed water is drained off. The swollen rice is cooked with steam at atmospheric pressure for 60 min,

Tofuyo in Japan,

Fig. 5 Red koji. Red mold rice, “red koji,” was prepared with *Monascus purpureus*

Tofuyo in Japan,

Fig. 6 Changes in temperature, moisture, pigment, pH, and acidity of red koji during cultivation. *Monascus* was cultivated at 32 °C for the time indicated. The steamed rice was inoculated with seed containing *Monascus purpureus*, and cultured in an incubation box. Koji samples were taken for analysis at the indicated time. -○-; Temperature, -●-; Moisture, -△-; Pigment, -□-; pH, -■-; Acidity

cooled until near body temperature, and then inoculated with a starter of the genus *Monascus* or *Aspergillus oryzae*. The inoculated rice is placed in wooden trays and further grown with fungus. Red koji grown with genus *Monascus* was harvested after cultivation at 32 °C for 7 days (Fig. 5) (Yasuda et al., 1983). Yellow koji grown with *Aspergillus oryzae* was prepared by incubation at 32 °C for about 48 h (Yasuda et al., 1981).

During cultivation of koji, temperature, moisture, and aeration are extremely important factors and have to be rigidly controlled for preparation of high-quality koji without contamination.

Changes in temperature, moisture, pigment, pH, and acidity of koji during the cultivation are shown in Fig. 6 (Yasuda et al., 1983). After 40 h of cultivation, the material temperature increased to around 40 °C. The temperature of koji was controlled by hand mixing. After about 50 h of cultivation, the moisture level was reduced to 30 % or less, and the koji materials were moistened by a sterilized water sprinkle. Consequently, the fungus growth and koji pigment formation were markedly enhanced. The pH and acidity of koji were not greatly affected during incubation. After cultivation for 7 days, the koji prepared with the genus *Monascus* was harvested for

making moromi (Yasuda et al.). At this point, the production of proteinase, α -amylase, and glucoamylase activities were maximal after the inoculation of seed culture (Yasuda et al.).

Koji is a source of valuable hydrolytic enzymes for converting starch into fermentable sugars and proteins into peptides and amino acids. The features of koji suitable for making tofuyo are as follows (Yasuda et al., 1981, 1983; Yasuda, Matsumoto, Sakaguchi, & Kinjo, 1995). It has high hydrolytic enzyme activities such as protease, amylase, and glycoamylase. Another is that it provides a good flavor and taste. In order to enhance production of enzyme activities and pigments, we examined the effect of steaming methods and rice varieties (Yasuda et al., 1983). In the system of steaming under atmospheric pressure, enzyme and pigment production of glutinous rice koji was higher than those of nonglutinous and broken rice koji. In contrast, in the system of steaming under barometric pressure conditions, the productivity of koji prepared with nonglutinous rice was more abundant than that of broken rice or glutinous rice. Although glutinous rice is traditionally used as a raw material for koji preparation, we found that the highest production of the enzymes and pigment was obtained by employing autoclaved nonglutinous rice (Yasuda, 1990; Yasuda et al., 1983). Yellow koji by *Aspergillus oryzae* with high enzyme activities was also obtained in the same manner as the case of red koji described above (Yasuda et al., 1981).

Soaking and Ripening

The last process of making tofuyo is to soak and to mature the dehydrated tofu cubes into the moromi. To prepare the moromi (soaking mixture; fermentation broth), red koji and/or yellow koji, awamori (43 % alcohol concentration), and a small amount of salt are mixed and stored at 4 °C for from 24 to 48 h. The mixture is then ground with a blender until mushy, and the result is called moromi. The dehydrated tofu cubes are immersed into the moromi, and they mature at from 25 °C to 30 °C for 5 months. The ethyl

alcohol concentration in the moromi is finally around 20 %, and the pH is from 5.6 to 6.0 throughout the ripening period. The fermentation and ripening of tofuyo are accomplished under a high alcohol concentration derived from awamori. The quality of the tofuyo product is finally affected by the variety of koji and the liquor in the moromi. According to our investigations, we confirmed that the tofuyo product with red koji or the mixed koji with red koji and yellow koji was superior to that of only yellow koji with respect to color and flavor (Yasuda et al., 1995). Awamori has also important roles for giving tofuyo a pleasant flavor and preventing contamination with putrefactive bacteria. Using other liquors for making tofuyo such as whisky and shochu did not give such a desirable effect for the flavor fermentation of the product.

Characterization of Tofuyo

Chemical Changes in Tofuyo During the Ripening Period

To clarify its scientific characteristics, we investigated the chemical changes in tofuyo during the ripening period (Yasuda & Kobamoto, 1994; Yasuda, Matsumoto, Sakaguchi, & Kobamoto, 1993). The typical fermented tofuyo after 3 month ripening is as follows: 29.2 % crude protein, 21.2 % crude fat, 7.4 % crude ash, 0 % crude fiber, 24.2 % reducing sugars, and 3.2 % salt (on a dry weight basis). Crude protein and crude fat contents of tofuyo decreased along with ripening as time advanced, but sugar content increased. Sodium chloride content of the product was virtually constant (around 3 %) throughout the ripening period (Table 1).

Amino acids in fermentation products greatly contribute to flavor formation. We analyzed changes in the free amino acids of tofuyo, which was prepared by using red koji during the ripening period (Katsura, 1996; Yasuda, 2010), and the data are shown in Table 2. A dramatic increase in particular free amino acids is involved in the flavor formation of tofuyo products during the ripening period. Especially glutamic acid, alanine, aspartic acid, glycine, and serine may

Total amino acids	174	544	1,499	3,176	4,720	5,154

contribute to the formation of a pleasant taste such as umami and sweetness. Furthermore, glutamic acid and aspartic acid contribute to produce a pleasant umami taste or savory enhancement in foods. In these data, the bitterness amino acids such as valine, isoleucine, leucine, tyrosine, phenylalanine, lysine, and arginine also gradually increased during fermentation, but the increased amount was much less than that of umami and sweetness amino acids.

Lioe & Yasuda (Lioe et al., 2004; Lioe, Apriyantono, Takara, Wada, & Yasuda, 2005) found that the presence of phenylalanine in savory fractions obtained from soy sauce is closely related to an enhanced umami taste in the fermented products. A potential synergistic effect of umami among free glutamic acid, salt, and phenylalanine was also observed (Lioe, Wada, Aoki, & Yasuda, 2007; Lioe, Selamat, & Yasuda, 2010). Furthermore, this phenomenon of umami or savory enhancement by subthreshold aromatic amino acids in soy sauce systems has been established by the model experiment system (Lioe et al., 2005). Although the efficacy of aromatic amino acids on umami or savory enhancement for the tofuyo product have never been investigated, the increment of these amino acids may seem to contribute to form the desirable taste and flavor of tofuyo.

Glucose is one of the major components apart from amino acids involved in the taste of the tofuyo product directly. The desirable taste of tofuyo is formed by interactions between these components. Glucose is produced by saccharification with the enzymatic actions of α -amylase and glucoamylase from koji (Tachibana & Yasuda, 2007). A similar phenomenon was also observed in the tofuyo products prepared using yellow koji and mixed koji (Yasuda et al., 1995, Yasuda, Matsumoto, Sakaguchi, & Kinjyo, 1994, 1995). Both α -amylase and glucoamylase produced by fungi had high activities throughout the ripening period despite the presence of high ethyl alcohol concentration from awamori. In fact, the reducing sugar contents of tofuyo increased with passage of the ripening period. Increase of glucose in the moromi is thought to be involved in the formation of its taste

components. Therefore, the saccharification ability by both enzymes also largely contributes to the formation of the desirable taste of the tofuyo product.

Recently, fermentation products have attracted attention as health-promoting foods. Especially peptides in fermentation products have the potential to prevent hypertension by inhibiting the angiotensin I-converting enzyme (ACE), which is a key enzyme for causing hypertension (Okamoto et al., 1995; Yang, Erdős, & Levin, 1971). Kuba, Tanaka, Tawata, Takeda, and Yasuda (2003) found ACE inhibitory activity (IC_{50} , 1.77 mg ml^{-1}) in extracts from tofuyo, and two ACE inhibitory peptides, IFL (IC_{50} , $44.8 \text{ }\mu\text{M}$) and WL (IC_{50} , $29.9 \text{ }\mu\text{M}$), were isolated to homogeneity. These peptides were expected to be easily absorbed by the gastrointestinal tract and to contribute to the antihypertensive effect via a transport system *in vivo* (Chun, Sasaki, Fujiyama, & Bamba, 1996; Kuba, Shinjo, & Yasuda, 2004; Kuba-Miyara & Yasuda, 2012). This finding suggests that previously unidentified bioactive compounds might be present in tofuyo and moromi. Therefore, tofuyo is expected to be beneficial as a health-promoting food.

Tombs in Ancient Egypt

Aidan Dodson

University of Bristol, Bristol, UK

An Egyptian tomb ideally comprised two basic parts. One was intended to house the body for eternity; the other was to act as the interface between this world and the next. These two elements could lie close to one another or could be separated by some considerable distance; they could also be of various constructional types and materials. However, the fundamental distinction remained between the mortuary chapel, or offering place, open to the public, and the burial chamber, intended to be sealed for eternity.

Theologically, since the dead were believed to dwell in the west, the western side of the Nile was the ideal place for a tomb. Accordingly, many necropoleis are to be found in this location. However, in a number of areas, this was not topographically practicable, tombs being placed on the east bank, in some cases with adjustments to ensure that the offering place of the public element faced west.

In the Nile Delta, however, the binary east/west bank division did not usually exist. Thus, while a cemetery might be placed to the west of the associated settlement, much depended on local topography, in particular the need to place cemeteries as far from the water table as possible. In a number of cases, particularly where a city hosted a royal cemetery, the necropolis was placed within the precincts of the principal local temple. This was also the case in some places in the Nile valley, in particular where the floodplain was particularly wide.

The public element of the tomb was usually focused on a stela, an inscribed slab that provided a point at which the two worlds met. It might be of simple form, bearing a depiction of the deceased (and perhaps his or her spouse) receiving offerings of food and drink, together with a ritual formula that guaranteed their eternal provision. On the other hand it might be an elaborately paneled “false door” (Fig. 1), making explicit the stela’s role as a portal between the worlds. In certain cases a statue of the dead person might replace or supplement the stela.

In many tombs the offering place comprised simply the stela, standing exposed, or with a very basic shelter carved out of the rock or built in brick or stone. However, in other cases the offering place was housed in a far larger structure, which could in turn be extensively decorated (Fig. 2). This structure may be referred to as a mortuary chapel or a mortuary temple, the latter term being generally used for royal examples.

For much of Egypt’s history, the decoration of such structures was concerned with food production, other motifs taken from the agrarian world,

Tombs in Ancient Egypt, Fig. 1 A typical false door stela of the Old Kingdom (British Museum EA682) belonging to Ptahshepses (ca. 2425 BCE) (Photo by author)

Tombs in Ancient Egypt, Fig. 2 The false door of Ptahhotep at Saqqara (ca. 2350 BCE) lies within a highly decorated chapel (Photo by author)

and the experiences of the deceased. In royal cases, this could include scenes of the gods and events of the reign. Tableaux in private chapels are often referred to as “daily life” scenes and provide an important source for our understanding of life in ancient Egypt. Their primary role was clearly to recreate magically the world the deceased had once enjoyed, as well as providing a further source of eternal sustenance. It seems likely, however, that they had other more esoteric significance, linked with concepts of regeneration and rebirth in the next world. From around 1250 BCE, these “daily life” scenes tend to be replaced by others of purely ritual type, with images of the gods and extracts from the various Egyptian funerary “books” that aided the dead person in his or her posthumous destiny.

As already noted, the form of the offering place varied. At one extreme, those of kings could be huge temples, either freestanding or, prior to the middle of the second millennium BCE, attached to a pyramid. Prior to the appearance of the pyramid, royal tombs seem to have

had a simple offering place adjacent to the burial chamber, and a large rectangular enclosure up to 1.5 km away, used during the funeral ceremonies, but dismantled afterwards. A mound of rubble or some other structure may have topped the burial place itself. At the beginning of the Old Kingdom (ca. 2650 BCE), these separate elements were united as a permanent monument in a single location, in the Step Pyramid complex of King Djoser at Saqqara. For perhaps the first time, all parts were built of stone, and a low square structure over the burial place was soon extended to form the basis of a six-stepped pyramid, the first of its kind (Fig. 3).

Only the very earliest pyramids were stepped, perhaps to provide a stairway to heaven for the dead king. They were soon replaced by smooth-sided structures (“true pyramids”), apparently intended as a recreation of the sun’s rays, along which the monarch might make his way to join with the sun god (Fig. 4). The very first step pyramids were surrounded by large rectangular enclosures holding ritual buildings (Fig. 5). However, these were soon superseded by a smaller enclosure with a mortuary temple on the east side of the pyramid. From this a causeway led to a “valley temple” on the edge of the desert (Figs. 6 and 7).

The free-standing temples that were adopted by the kings of the New Kingdom (1550–1070 BCE) after the royal abandonment of pyramids were all but indistinguishable from contemporary temples of the gods, the differences being in detail only (Figs. 8 and 9). Unlike earlier mortuary temples, the king’s spirit now shared the temple with Amun, the King of the Gods, and the sun god, Re, each of whom had his own separate sanctuary within the temple. They are thus often distinguished from the earlier temples by the description of “memorial temples.”

Private individuals’ mortuary chapels fall broadly under three headings. One type is built against or within *mastabas*, stone or brick structures shaped like low benches (“mastaba” means “bench” in Arabic). They are used throughout Egyptian history at sites with a flat basic topography, although the best-known date to the Early Dynastic Period and Old and Middle Kingdoms (ca. 3000–1700 BCE).

Fig. 5 Plan of the Step Pyramid complex, showing the great expanse of ritual buildings (Plan by author)

Tombs in Ancient Egypt, Fig. 6 Typical of later pyramids is that of Sahure (ca. 2465–2450 BCE), with a mortuary temple on the east side (Photo by author)

Tombs in Ancient Egypt, Fig. 7 This shows the layout of the whole complex of Pepy II (ca. 2290–2180 BCE); the small pyramids belonged to his wives (Plan by author)

Mastabas of the earliest times usually had a paneled exterior, but from the Old Kingdom onwards, they tended to have flat, slightly sloping, sides, although paneling is occasionally found down into the Middle Kingdom (2100–1700

BCE). Chapels range from a simple niche at the southern end of the eastern face, holding the stela, to a complex of a dozen or more decorated rooms occupying much of the interior of the mastaba. Most usual is an offering place with one or two rooms (Figs. 10, 11, 12, and 17).

The next type of mortuary chapel is also employed on flat sites but comprises a freestanding building without an associated mastaba. Once again, these can vary considerably in size and elaboration, from little more than a shed around the stela to a miniature temple. The latter seem to appear first late in the Eighteenth Dynasty and are referred to as “temple tombs” (Fig. 13).

The final form of mortuary chapel is that which is cut into a rock face (Fig. 14). Such offering places first appear around 2500 BCE at Giza, and are found throughout the rest of Egyptian history. Plans are almost infinitely variable, although a number of fairly standardized plans are to be seen at Thebes during the New Kingdom (1550–1070 BCE). In particular there is the T-shaped tomb, with a broad but shallow hall running across the axis and a long corridor running from the middle of its back wall to the offering place, deep in the rock. This basic form could be greatly elaborated by the addition of columns and further chambers – one had no fewer than 70 columns.

Tombs in Ancient Egypt, Fig. 8 The earliest surviving New Kingdom royal mortuary temple is that of Queen Hatshepsut (ca. 1472–1457) at Deir el-Bahari (Photo by author)

Tombs in Ancient Egypt, Fig. 9 Of rather different appearance but with the same purpose is the temple of Ramesses III (ca. 1185–1153 BCE) at Medinet Habu (Photo by author)

Tombs in Ancient Egypt, Fig. 12 The most elaborate chapel within a mastaba is that of Mereruka (ca. 2340 BCE) at Saqqara (Plan by author)

Of course, this division is purely for convenience, and many tombs exist that are a combination of more than one category. In particular, rock-cut mortuary chapels could have freestanding courtyards built in front of them (Figs. 15 and 16). Particularly elaborate examples date to the Saite Period (663–525 BCE).

In addition, after the abandonment of pyramids by kings, miniature examples often appeared above private sepulchres, of both built and rock-cut designs.

The burial chamber and its associated elements are collectively known as the “substructure.” The two key types are those approached via a vertical shaft and those accessed by sloping passage or stairway. A further consideration is whether the substructure has been tunneled out of the living rock or whether it has been constructed out of stone or brick in a cutting in the desert surface and subsequently covered over. There are, however, tombs that use more than one approach to various elements of their substructures.

In the vast majority of Egyptian tombs, the substructure lay close to, or directly under, the offering place. Many Old Kingdom mastabas had shafts descending from their roofs to burial chambers in the rock below (Fig. 17), while royal pyramids usually had their burial chamber under the center of the monument, approached via a sloping corridor from the center of the north face of the pyramid. In rock-cut mortuary chapels, sloping passages are found in the earliest examples, but later shafts are used as well.

Occasionally, the substructure lies some way from the offering place. The best examples of this are the royal tombs of the New Kingdom at Thebes, where the mortuary temples lay on the edge of the desert, but the tomb chambers were up to 2 km away in a desert valley. This is now known as the Valley of the Kings and also held

Tombs in Ancient Egypt,

Fig. 13 Plans of the “temple tombs” of Maya and Tjia at Saqqara, ca. 1340–1240 BCE. Note the pyramid attached to the rear of the lower sepulchre (Plan by author)

Tombs in Ancient Egypt,

the burial chambers of a handful of highly placed nobles, whose rock-cut mortuary chapels lay a similar distance away.

Substructures took a variety of forms, ranging from a single chamber and approach shaft/corridor to a long sequence of corridors, pits, and halls. In the Nile valley, substructures were usually tunneled into the bedrock or constructed within trenches cut in the rock. However, in the Delta, where the bedrock was below the water table, constructed chambers were always used, sunk as deep as possible without getting too close to the water table, since damp was fatal to the preservation of the mummified body and its accompanying equipment.

While most substructures were simple, with an approach shaft or passage leading to a room

whose door was simply blocked after burial, some included special security features, with sliding trap doors, hidden entrances, and/or burial chambers cut from single blocks of stone, closed with the aid of a “hydraulic” system using sand. Such elaborate features were first employed during the late Twelfth Dynasty (ca. 1800 BCE) and then revived over a millennium later, during the Saite Period.

Royal tombs were not surprisingly among the sepulchres with the most elaborate substructures, although certain private examples, particularly of the Saite Period, exceeded even them. Many earlier pyramids had a standardized substructure, built of stone in a shallow cutting, with a group of three chambers reached by a long corridor. This was blocked by three vertical portcullis

Tombs in Ancient Egypt,

Fig. 15 Plans of the private tombs of Paser, Setau, Roma-Roy, and Heqamaatrenakhte at Thebes during the middle of New Kingdom (ca. 1300–1150 BCE), showing the relationship between the mortuary chapel, in some cases pyramid, and the substructure (Plans by author)

slabs of granite (Fig. 7). From the middle of the Middle Kingdom, however, changes were brought in to increase security. Entrance locations became random, and the aforementioned security arrangements introduced.

The security imperative probably also lay behind the separation of the royal burial chamber from the mortuary chapel early in the New Kingdom. The Valley of the Kings tombs generally take the form of a set of passages and stairways, leading to a pillared antechamber, and finally to a pillared burial chamber. A shaft in the floor interrupted progress down the tomb, probably with a dual role of hindering thieves and preventing storm water's penetrating the inner rooms (Fig. 18).

In contrast to the mortuary chapel or temple, which almost always had some form of

decoration, the substructure was usually completely plain. The principal exceptions were the royal tombs of the late Old Kingdom and the New Kingdom onwards, and a handful of private sepulchres of the Sixth Dynasty, Middle Kingdom, New Kingdom and Saite Period. In the late Old Kingdom, royal burial apartments were adorned with the *Pyramid Texts*, magic formulae intended to aid the king in the next world. They are the ancestors of a whole series of “books” that formed the basis for all later substructure decorations.

Royal tombs of the New Kingdom and later were principally adorned with various heavily illustrated compositions relating to the sun god's nocturnal journey through the underworld, in which the dead king would participate (Fig. 19). At first these works were a royal

Tombs in Ancient Egypt, Fig. 16 One of the largest and most elaborate tombs in Egypt belonged to the priest Pedamenopet (ca. 600 BCE). It was partly built of brick and partly rock cut, with an extremely elaborate substructure. The burial chamber was carefully concealed and was approached from below (Plan by author)

prerogative, but by Saite times they could also be found in private tombs as well, which also revived the ancient *Pyramid Texts*.

The rare Old Kingdom decorated private burial chambers generally had illustrated lists of offerings on their walls. This was also the case in the Middle Kingdom, but in the New Kingdom the main decorative composition was the *Book of Coming Forth by Day* – better known as the *Book of the Dead*. This was essentially a guidebook to the next world and was more usually found on a papyrus placed alongside the mummy. Extracts are also found in mortuary chapels of the Nineteenth Dynasty and later.

Following the Macedonian and Roman takeovers of the country, Egyptian-form tombs were supplemented by those in the classical tradition, in particular at Alexandria and in other areas with high levels of European settlement. However, even these sepulchres often included Egyptian features, especially in their decoration, where the native gods often appeared. A key difference between the two mortuary traditions was the blurring of the previous rigid distinctions between the chapel and the burial place. In classical tombs the body was placed in a sealed loculus in the wall of a generally accessible catacomb that might include both a chapel and a room for funerary feasts.

Tombs in Ancient Egypt, Fig. 17 Plan of the tomb of Kawab at Giza (ca. 2530 BCE), showing the burial shafts descending through the superstructure and the chapel built partly within and partly outside the mastaba (Plan by author)

Tombs in Ancient Egypt,

Tongren Zhenjiu Shuxue Tujing

Richard Bertschinger

The *Tongren Zhenjiu Shuxue Tujing* (Illustrated Canon of Acupuncture Points based upon the Bronze Figure) was written by Wang Weiji, and published in AD 1026. It has been a baseline in the identification of acupuncture points ever since. It is used not only in Chinese medicine, but also in acupressure as developed recently in the West, in *shiatsu* (pressure point massage) in Japan during this century, and in all acupuncture-related disciplines.

By the Song Dynasty (AD 960–1126), after much copying and recopying, the locations of the points and channels had become confused. Because of this and the greater stability brought about by the Song reunification of the empire, the medical scholar Wang Weiji reorganized and

collated all the then available material in order to locate and define the points precisely.

He produced a book which very quickly became the authoritative text throughout the country. It gave very detailed and accurate information concerning the points, the channels, the depths and effects of needling. The total number of points named in the ► [Huangdi Neijing](#) (Yellow Emperor's Canon of Medicine) had been 160; in the *Zhenjiu Jiayi Jing* (A-Z of Acupuncture and ► [Moxibustion](#)) it was 349. But now it was raised to 354. Not long afterwards, the full text of this book was cut onto two stone tablets, each some 2 m high and 7 m in length, which were erected in the Song capital, Kaifeng, where they could be read by everyone, or where ink-impressions could be made from them.

At the same time Wang Weiji directed the casting of two life-size bronze figures – hence the title of his book – which were completed in 1027.

These bronze figures are the very earliest of their kind. They were hollow and had the exact locations and names of the acupuncture points marked on their surface. It is noted in the Song histories that the purpose of the figures was for them to be covered in beeswax and then filled with water. When a student palpated and punctured a point correctly, a stream of water would flow out, reminiscent of the energy stream (or *qi*) tapped by that particular point.

The later history of these figures and tablets is also revealing. After 200 years, when the Yuan Dynasty moved the capital to what is now Beijing, the bronze figures and tablets were also moved, to take pride of place in the temple at the new Imperial Medical College. However, much use had been made of the figures, and the tablets were so worn that they were indecipherable. Reproductions were therefore made again. During excavations from 1965 to 1971 in Beijing, fragments of the original Song tablets were discovered, and their texts shows that the tradition has been faithfully and accurately preserved to the present day. This book is used as the foundation text for the listing of points in the *Essentials of Chinese Acupuncture* (Beijing, 1980) and other texts which have all been recently produced

in China and which are aimed at the interested acupuncture audience in the West.

Tool Recycling in India

Babul Roy

Social Studies Division, Office of the Registrar General, India, New Delhi, India

Antiquity of Tool Recycling

Recycling of discarded utilitarian items as raw materials in fresh manufacturing is common in today's industrial world. And that the reusing of the discarded items for purposes different than they were originally used or for the same purposes, either by the same users or by altogether different users, is also common. Such evidences from the prehistoric past remained unknown until recently when it has been convincingly established that during the Stone Age, such practices not only happened but also were far more extensive and widespread, and they played quite significant role in prehistoric assemblage formation. In a Research Workshop organized by *The Israel Science Foundation* in 2013, several papers were presented on stone tool recycling during the early Stone Age (<http://earth911.com/tech/prehistoric-recycling/>). Evidence found in Fuente Nueva, southern Spain, although not very convincing, suggest that stone tool recycling may date as far back as 1.3 million years ago (Barsky et al., 2014).

Although the practice of tool recycling in prehistoric culture has only recently been

established, scavenging of stone tool remains, and their reuse by native Indians during the contact period all through the New World, by the Australian aboriginals, and by many native Indians in isolated pockets in Asia and Africa are now well established in prehistoric literatures (Cane, 1992, p. 26; Daniel et al., 2007; Galup, 2007; Goodyear, 1979; Kardulias, 2009; Sampson, 2009; Silliman, 2003). Scavenging of exposed prehistoric sites for suitable raw material by contemporary tribal people for modern uses (uses different from those of the original stone tools) is, however, a more commonly reported phenomenon from many parts of the world. The frequent uses of recycled stone tools collected from exposed prehistoric sites by contemporary tribesmen in several modern uses (e.g., strike-a-light set, folk surgery, etc.) are reported from many Southeast Asian regions, such as Borneo, Indonesia, India, and Sri Lanka (Brumm, 2006; Roy, 2009).

During the 1970s, Professor Lewis Roberts Binford (1931–2011) popularized the concept of “curation and recycling” in prehistoric archaeology. However, this issue generally has evaded serious archaeological interest until recently when convincing evidence established such prehistoric engagements to be far more extensive than ever realized, and their actual significance in archaeological interpretations is now understood. The problem of identifying the recycling evidences in prehistoric material remains perhaps was the main reason for not getting enough attention of archaeological investigation, which involves both the primary (reused in the same way as it was earlier either directly or by rejuvenating the cutting or working edge) and the secondary (the recycled material is put into altogether a different product, such as using as raw material for fresh knapping – striking a piece of stone to make weapons) recycling activities. In prehistory, both these conditions are difficult to establish. In the first instance, it is not easy to distinguish an existing tool that had been rejuvenated again and again during its lifetime by the user from that of a discarded tool that had been

reused/recycled by later users either immediately or after several years of disposal. In the second instance, the identification of recycling could be difficult in all such cases where the discarded tools of earlier age had been reused or recycled to shape completely new items destroying all obvious features of their earlier use.

Tool Recycling in Prehistoric India

A series of prehistoric archaeological sites bearing micros or microliths (very small size stone tools typically belonging to the Mesolithic period of the Stone Age) have been discovered in the district of Mandla (22° 12' to 23° 22' N, 79° 57' to 81° 45' E), Madhya Pradesh, in India during 2001–2002 (Roy, 2003, 2008, 2009, 2011, 2012). The Mandla findings are an important addition to the numerous prehistoric sites already discovered in the Chota-Nagpur belt (Jharkhand) and the adjacent geography now found across the States of Odhisa, Chhattisgarh, and Madhya Pradesh (Figs. 1 and 2). The discovery of the Mandla archaeological sites is significant for two reasons – first for having clear evidence of continuity of the microlithic tradition until recent historical time (late nineteenth or early twentieth Century) and second for convincing evidence of using recycled stone tools in prehistoric tool-making practices. This is the first time that evidence of stone tool recycling in prehistoric culture was reported from India. The evidence of patinated dorsal features (flake scars) from previous use along with comparatively fresh flaking marks on the same specimen confirmed recycling practices. Large tools discarded by earlier users were reused as raw materials for microlith production. It is often difficult to determine whether the old patinated surface is actually an earlier flake surface or is in fact a natural rock face. Moreover, historical contamination in case of open-air deposits, although all archaeological sites are now believed to remained exposed – at least for a brief period of time before undergoing stratification – can also make the situation

Tool Recycling in India, Fig. 1 Prehistoric sites in the Indian subcontinent in 1947. Since then more sites have been added, a large number of which come from the contiguous geography located across the adjoining States of Odhisa, Chhattisgarh, and Jharkhand. Mandla sites

discovered during 2001–2002 are further added to the list of prehistoric sites in India (Credited to V. D. Krishnaswamy, “Stone Age India”, Ancient India 3:11–57, 1947)

confusing. In Mandla, India, a core made on a recycled artifact is a confirmed case. The striking platform of the specimen undoubtedly bears old flake scars of an earlier artifact (Fig. 3). Once this was confirmed, several artifacts of Mandla findings, which were possibly made on recycled materials, were rather easily segregated (Figs. 4, 5, 6, and 7).

Tool Recycling: Implications in Prehistory

The Stone Age economy of using the easily available large tool remains as raw materials, particularly in subsequent small tool using cultures, has implications in our general interpretation of prehistoric cultures. The question is whether the

Tool Recycling in India,

Fig. 2 Partala prehistoric site in Mandla. The site abounds with natural pebbles and rocks scattered all around, a commonly occurring scenario in the district (*Inset*) Prehistoric artifacts are occasionally found in the open along with scattered natural pebbles and rocks

Tool Recycling in India, Fig. 3 An exhausted stone core on recycled material (secondary recycling) – (a) top, (b) side, and (c) bottom views (Scale: bar stands for 2.5 cm). The striking platform bears patinated flake scars from previous use. Relatively fresh flaking marks (miss-hits

and step flaking marks) from latest use are found around the edges of the striking platform (This and all other photographs/figures, if otherwise not mentioned, are by author)

culture in question was largely or exclusively based on any earlier cultural ruins. Any prehistoric engagement must involve this particular issue, as the same may influence the reading of prehistoric records to a considerable extent. In

Tool Recycling in India, Fig. 4 Use of recycled tools by fresh trimming of the working edge (primary recycling). The recycling practice is confirmed by double patination – fresh and old of considerable time gap

India, recycling evidence in prehistoric assemblage may not be so lacking, but has probably remained unnoticed in archaeological interpretations so far. The discovery of Mandla may influence further study in this direction. And since most of the prehistoric sites in India are exposed to the open air without reliable dating clues, the evidence of recycling may guide further understanding of the chronology problem.

How extensive the practice of using recycled large tools in small tool (micros) manufacturing remained in prehistoric practice might judge the extent of destruction of the large tool cultural remains by subsequent small tool makers. In Mandla, hundreds of stone tools have been recovered bearing signs of being prepared from recycled large tools of earlier times. Thus, the large tool cultural remains of earlier phase had possibly been destroyed by subsequent small tool makers. Archaeological sites or cultural remains whether are based on ruins of earlier cultures must be carefully investigated to understand the Stone Age history of a region or the local cultural

Tool Recycling in India, Fig. 5 Use of recycled tools after considerable reworking, such as the entire working edge made afresh (primary recycling). The recycling practice is confirmed by double or multiple patination of

considerable time gap. (a) and (b) are two sides of the same specimen, (c) fresh working edges, and (d) long flake tool recycled after reworking the working edge

Tool Recycling in India, Fig. 6 Use of recycled tools as raw material in fresh knapping (secondary recycling), (b) is a recycled flake used as side scraper by making the working edge fresh. The rest of the figures are cores made on recycled materials. Large tools of an earlier

phase were reused in fresh microlith manufacturing. The process destroyed the original specimen completely, rendering the original tool unidentifiable, particularly when the natural rock surface and the old knapping scars are not clearly distinguishable

chronology. This has general methodological significance in the interpretation of archaeological records.

The evidence of using large tool remains from earlier tradition by subsequent small tool makers may not be easily found when the very process of small tool knapping would destroy any evidence of large tools being recycled in the process. In India, the microliths or small tool remains are found to be more numerous compared to the large tools of preceding periods. Is this due to a sudden increase in population during the microlithic time? Or might it be due to destruction of the earlier large tool remains by subsequent

microlith users? This will remain a challenge in coming years in Indian prehistoric engagements. The significance of “recycling” in prehistoric archaeological interpretation has received more attention in recent times, and several methodological approaches are suggested to address the inevitable problem in studying recycling attributes in prehistoric cultures. Analysis of bipolar technique, refitting, and analysis of spatial data are demonstrated to be useful in interpreting recycling behavior, which is now considered to have far reaching knowledge in prehistoric assemblage formation (Amick, 2007; Vaquero, 2011; Vaquero et al., 2012).

Tool Recycling in India,

Fig. 7 Successive reuses over a long time line is evident from multiple patination. The specimen bears at least three levels of patination formation – fresh working edge, old patinated flake scars (fs), and very old patinated body of the specimen (a) and (b) are close views of the working edge of the specimen.

Tools Used in Ancient Egyptian Construction

James A. Harrell

University of Toledo, Toledo, OH, USA

Building Materials

Most ancient Egyptian buildings were constructed of either mud bricks with wood elements or wattle-and-daub walls of intertwined poles packed with mud. These include all the houses and even the royal palaces. In the better-built structures, mud bricks were used for the foundations and walls with wood planks and poles employed for most everything else, including door and window frames, doors, window shutters, vertical supports (pillars) for roofs and upper floors, and horizontal supports for the mud-brick walls. Gypsum plaster was sometimes used to cover the interior walls and stone was also employed in these buildings whenever extra strength and durability were required, such as for door thresholds and pillar bases. The only buildings constructed largely or entirely of stone were the temples and freestanding tombs (pyramids and mastabas), although some of these were also built of mud brick, and many stone temples were surrounded by massive mud-brick walls.

Tools Used in Ancient Egyptian Construction, Table 1 Ancient Egyptian chronology

Predynastic or Neolithic period (5500–3100 BCE)
Dynastic or Pharaonic period (3100–332 BCE): dynasties 1–30
Early dynastic period (3100–2686 BCE): dynasties 1 and 2
Old kingdom (2686–2160 BCE): dynasties 3–8
First intermediate period (2160–2055 BCE): dynasties 9 to early 11
Middle kingdom (2055–1650 BCE): dynasties late 11–14
Second intermediate period (1650–1550 BCE): dynasties 15–17
New kingdom (1550–1069 BCE): dynasties 18–20
Third intermediate period (1069–664 BCE): dynasties 21–25
Late period (664–332 BCE): dynasties 26–30
Greco-Roman period (332 BCE–395 CE)
Ptolemaic period (332–30 BCE)
Roman period (30 BCE–395 CE)

The construction tools considered here were in use during Egypt’s Dynastic period (Dynasties 1–30), which ranged from about 3100 to 332 BCE (Table 1). The subsequent Greco-Roman period is excluded because many of the tool designs (and construction practices) were imported from the Greeks and Romans. Although there are no ancient Egyptian texts describing the use of construction tools, many of the tools themselves have survived, and there are also numerous carved reliefs and painted scenes on the walls of tombs showing the tools in use (Arnold, 1991; Clarke & Engelbach, 1930; Gale et al., 2000; Kemp, 2000; Petrie, 1917). Two such tombs are especially noteworthy in this regard, those of (1) Ti, an overseer of pyramids and temples under three fifth Dynasty kings (late Old Kingdom) at Saqqara near Cairo (Epron, 1939; Wild, 1966), and (2) Rekhmira, a vizier under two eighteenth Dynasty kings (early New Kingdom) at Qurna near Luxor (Davies, 1943). It is the art in these tombs that supplied the representations of tool use in Figs. 1–17. Another source of information comes from experimental archaeology, where facsimiles of ancient tools are made and then used to test their efficacy in various applications and materials (Stocks, 2003).

Measuring Tools

Construction, especially of the more elaborate stone structures, required the use of a variety of measuring tools, including ones for determining distance, slope, and flatness (for examples of these tools, see Pls. 47–49 in Petrie, 1917, Figs. 264–265 in Clarke & Engelbach, 1930, and Figs. 6.1–6.9 in Arnold, 1991). The Egyptians had cubit rods and measuring cords for determining distances. The cubit was a standard unit of distance that varied slightly during the Dynastic period but averaged 52.5 cm. It was divided into seven palms, each of which was further subdivided into four fingers. The working cubit rods were carved from wood (ceremonial ones were often of stone), and some could even be folded along hinges. Measuring cords were used to mark off both short and especially longer distances, and these were subdivided by knots tied at fixed multiples of cubits (Fig. 1).

Squared edges and corners were achieved through the use of a builder’s square, which consisted of two straight lengths of wood joined at their ends to form a right (90°) angle (Figs. 2 and 7). The square level combined a builder’s square with a plumb bob. It had two perpendicular sides of equal length that were joined by a crosspiece. At the apex, where the two joined sides met, there was an attached cord with a plumb bob suspended from the other end. The conical plumb bob was typically carved from stone. In use, the square level was placed upright on a surface (perpendicular to it), resting on the free ends of its two sides. By noting where the cord with the plumb bob lay on the crosspiece, the slope of the surface could be ascertained. Plumb bobs suspended from long cords were used to mark straight lines on vertical surfaces, check the verticality of walls, and measure vertical distances. A tool called a plumb rule was also employed to determine verticality. This consisted of a flat wood plank with two short shelves of equal depth at one end. A cord was attached to the end of the plank, just above the shelves, and this was threaded through a diagonal hole in the top shelf that exited at its outer edge. A plumb bob was suspended from the cord’s other end. To use

ochre) and then pulled taut across the surface. By flicking the cord against the surface, a straight line was marked off.

A set of leveling (or boning) rods was used to ascertain the flatness of a stone surface (Fig. 1). The set's three or four short wood rods were of identical length, and two of these were joined at their tops by a cord with the others left unattached. Two workers, each holding one of the joined rods, would place their rods upright

(perpendicular to) the surface and then pull the cord taut. With their free hands, or with the assistance of a third worker, the loose rods were placed upright on the surface and moved along the stretched cord. Wherever one of these rods fell below or rose above the cord, a departure from flatness was indicated. Areas that were too high were probably marked with colored paint or powder to show where additional dressing of the surface was needed. The degree of flatness of

a small surface could also be determined with a straightedge, which was a long piece of wood with a linear edge (Fig. 2).

Cutting Tools

Stone Versus Metal

The first tools used in ancient Egypt, and volumetrically the most common ones employed throughout the Dynastic period, were made of stone. Tools requiring a hard, sharp edge or point were fashioned from chert (also known as flint), a rock consisting of microcrystalline

quartz. These were used to cut wood and also probably sometimes soft stones (limestone, sandstone, travertine, and rock gypsum). Hard stones with good impact-fracture resistance (notably anorthosite gneiss, dolerite, and silicified [quartz-cemented] sandstone or quartzite) were employed for pulverizing and grinding the hard stones, including anorthosite gneiss, basalt, granite, granodiorite, metagraywacke, and siliceous sandstone among a few others.

Copper tools, like those of stone, predated the Dynastic period. Because copper is a very soft metal, it could only be used to cut wood and soft stones and being much costlier than stone it was

Tools Used in Ancient Egyptian Construction, Fig. 11 Woodworker using an adze. Redrawn from a relief carving in the tomb of Ti (fifth Dynasty). Note the axe at the top (From Wild (1966, pl. 174))

used sparingly for tools and then just for the more important projects. The much harder bronze metal (copper alloyed with tin) was first introduced during the Middle Kingdom and became the predominant material for metal tools beginning in the New Kingdom. Even though much harder than copper, bronze was still too soft to use on hard stones and for these the stone tools were still preferred. Iron tools first appeared in the Late Period. Although usually described as consisting of iron, these tools were actually made from either a primitive kind of steel (iron alloyed with carbon) or case-carburized wrought iron. Iron tools were strong enough to work the hardest materials and quickly replaced the stone tools formerly employed.

Stone Tools

Stone mauls were elongated, generally roughly shaped pieces of hard stone with a blunt tip and a pinched waist where a wood handle was attached (Fig. 3). In contrast to this hammer-like tool, stone pounders were handheld, compact

pieces of hard stone that became well rounded and often nearly spherical after extended use (Fig. 4; for examples of these tools, see Pl. 53 in Petrie, 1917, Fig. 266 in Clarke & Engelbach,

1930, and Figs. 6.12–6.17 in Arnold, 1991). Both tools cut stone by pulverizing it. They were used to work soft as well as hard stones, but saw their greatest application with the latter.

Rubbing stones were employed for smoothing both stone and wood surfaces (Figs. 4–7). These were the same hard stones used for mauls and pounders, but silicified sandstone was especially favored for this application. Only the harder stones can take a polish, and smoothing with rubbing stones was the first step. Producing a good, reflective polished surface required rubbing with an abrasive paste. Quartz sand was almost certainly the abrasive used, and this would have been applied with either a piece of leather or cloth (Figs. 3 and 4). Using progressively finer-grained sands would produce an increasing degree of polish.

Hand-cranked stone drills were used to hollow out the interiors of stone vessels and may have had some construction applications as well (Figs. 8 and 9). The drill consisted of a wood shaft with a forked end into which was lashed a bit of either silicified sandstone or, more often, chert. The other end of the shaft was bent to form a handle, and suspended just below this were stone weights that served to increase the downward cutting force of the bit. By cranking the handle back and forth, a worker could drill a cylindrical hole.

Chert is the only native Egyptian stone that can be shaped into a tool with hard, sharp points and edges. It was consequently widely utilized for a wide variety of nonconstruction applications, such as arrow and spear points and knife and sickle blades. In woodworking, chert was used for axe and adze blades, but it is unclear whether this stone was also used in stoneworking. It has been shown experimentally that chert pick heads, adze blades, and chisels can easily cut the softer stones (limestone and sandstone), and chert gravers (sharp-pointed inscribing tools) can be used to incise both soft and hard stones. Although there is no direct archaeological evidence for such applications, it seems likely that chert was employed for stoneworking.

Metal Tools

The principal metal tool used for stoneworking during the Dynastic period was the chisel

sleepers (or rollers?; *upper right*). Redrawn from a painting in the tomb of Rekhmira (eighteenth Dynasty) (From Davies (1943, pl. 58))

(Figs. 1 and 4). Copper and bronze chisels were formed from stout cylindrical bars with either a pointed or flat-edged tip and were struck with a wood mallet (for examples of chisels and mallets, see Pls. 21–22, 46 and 49 in Petrie, 1917, Figs. 263–264 in Clarke and Engelbach, and Figs. 6.10 and 6.18–6.19 in Arnold, 1991). Some, especially for woodworking, were fitted

with a wood handle (Figs. 7 and 10). The chisels were used to dress soft stones and to cut holes and grooves in wood. Even for such soft materials, the tips needed frequent sharpening. It was not until the advent of iron chisels (and the first metal hammers) during the Late Period that the hard stones were worked with metal tools. Copper and bronze gads resemble chisels but were not used

Tools Used in Ancient Egyptian Construction, Fig. 17 Workers pulling a sledge with ropes while another worker pours water on the ground in front of the

sledge. Note the rounded front and chamfered rear of the sledge runner. Redrawn from a relief carving in the tomb of Ti (fifth Dynasty) (From Epron (1939, pl. 52))

for cutting. They were instead hammered into existing cracks and fractures within wood or stone in order to split these materials. The woodworkers also used a gouge, which was a small handheld, chisel-like tool for cutting grooves (Fig. 6).

Adzes are essentially flat chisels with a broad, straight cutting edge that were mounted on the end of a hooked wood handle (Figs. 2, 6, 7, 11, and 12; e.g., see Pls. 15–18 and 55 in Petrie, 1917). Blades of both metal and chert were employed. Adzes were used for trimming wood, and although direct evidence is lacking, they may also have been used for dressing soft stone surfaces.

Copper and bronze saws were employed for cutting wood and stone (Figs. 2, 6, 7, 10, and 13; e.g., see Pl. 50 in Petrie, 1917). Those with a serrated blade cut both wood and soft stone, whereas saws with smooth, nonserrated blades were used to cut the hard stones. In the latter case, the cutting was not done by the metal

blade itself (unlike the serrated blades used for softer materials) but rather by a quartz sand abrasive that was fed into the saw cut and over which the metal blade moved. Weights were normally attached to the ends of the longer saws of both types in order to increase the downward cutting force. Although iron saws eventually replaced those of copper and bronze, the basic designs did not change: serrated blades for soft materials and nonserrated blades for hard stones.

Bow drills with an abrasive bit (bit drills) were used to cut holes through wood and soft stones (Figs. 6, 7, and 14; e.g., see Pl. 48 in Petrie, 1917). The drill consisted of a wood shaft into one end of which was fitted a solid metal or chert bit. A bow strung with cord (similar to those wielded by archers) was used to rotate the drill shaft. This was accomplished by tightly looping the bow cord around the shaft and then moving the bow back and forth. While operating the bow with one hand, the worker used his other hand to hold onto a loosely fitting, hemispherical wood or stone cap

on top of the drill shaft. Such drills were much used in woodworking to produce the holes for doweled joints and lashings. In place of the solid bit, other bow drills were fitted with a hollow metal tube (tube drills). Unlike the bit drill, where the bit itself does the cutting, the tube drill used a quartz sand abrasive fed into the bottom of the hole. As with the nonserrated saw, it was the quartz sand that did the actual cutting, thus making the tube drill suitable for hard stones. Both types of drills originally had copper or bronze fittings with later ones made of iron.

An especially important tool for woodworking was the axe, which was used to chop and cleave wood (Figs. 7 and 12; e.g., see Pls. 1–7 in Petrie, 1917). Axes had either a subcircular or subrectangular metal blade that flared out into lugs on the dull side that were used in lashing the blade onto a wood handle.

Tools for Mud-Brick Manufacturing

Mud bricks were made from a mixture of fine-grained sediment (especially clay-rich mud), sand, chopped straw or other plant chaff, and perhaps also, as in modern-day Egyptian mud bricks, animal manure (Fig. 15). Excavation of the sediment and mixing the ingredients was done with the same hoe used by the ancient farmers. The wood blade of this tool had a narrow extension or tang on one side and this was fitted into a hole cut through one end of a short wood handle, with the two parts lashed together (Fig. 15; e.g., see Pl. 68 in Petrie, 1917). The mud mixture was typically packed into wood molds to produce bricks of uniform size (e.g., see Fig. 263 in Clarke & Engelbach, 1930). After drying and hardening in the sun, the bricks were ready for use.

Moving Tools

The construction of stone buildings required the lateral movement and lifting of stone blocks weighing anywhere from a few tons to tens (and exceptionally hundreds) of tons. Nearly all of this work was done with ropes, levers, and sledges

combined with a large measure of human muscle. The ancient Egyptians had ropes made from a variety of materials, including palm fibers, grasses, and papyrus and other reeds. Ropes up to several centimeters thick have been found and would have been strong enough for the heaviest loads. These were sometimes used in conjunction with grooved bearing blocks, which were carved from wood or stone and served as rope guides. By draping a rope around this device, the workers were able to pull from an angle (e.g., see Figs. 6.45–6.46 in Arnold, 1991). There were no pulleys in Dynastic Egypt.

Stout wood poles or beams were employed as levers for shifting stone blocks (Fig. 16). The largest were operated by teams of workers who would pull down on the elevated end with attached ropes. Stone blocks sometimes had small recesses (lever sockets or holes) cut along their sides where the lower ends of levers could be inserted (e.g., see Fig. 6.26 in Arnold, 1991). Wood or stone fulcrums were placed under the lower end of these levers, and wedge-shaped pieces of wood were pushed under the levered-up edge of a block to allow deeper insertion of the lever (e.g., see Fig. 267 in Clarke & Engelbach, 1930, and Figs. 6.42–6.43 in Arnold, 1991).

Sledges made from wood were employed for moving heavy loads around the construction site (Figs. 16 and 17). This conveyance consisted of two parallel runners joined by a series of crossbeams (e.g., see Figs. 6.35–6.36 in Arnold, 1991). Along the sides, on top of the runners, wood stakes or other attachments would have been present to restrain the load or anchor tie-down ropes. The front ends of the runners were rounded and angled upward to allow the sledge to ride up and over irregularities in the ground. The back ends of the runners were often chamfered (beveled) with a cut angling downward toward the front of the sledge (as in Fig. 17), and these allowed the insertion of levers to help move the sledge forward or adjust its direction. Using attached ropes, the sledges were pulled by teams of men or, less often, draft animals.

In order to reduce ground friction, the sledges were pulled over either wetted ground or wood beams (sleepers) laid crosswise along the

sledge's path (Fig. 16). It has been suggested that the sledges were also sometimes pulled over wood rollers, but this is unlikely as rollers would only be effective on ground that was hard, smooth, and relatively flat. Even though the Egyptians knew about the wheel from earliest Dynastic times, they had no wheeled wagons until the early New Kingdom. From this time onward, wagons may have been used for hauling stone blocks, especially the smaller ones, but sledges almost certainly remained the main conveyance for moving blocks around the construction site.

Wood rollers were apparently sometimes placed directly under stone blocks when these were being moved across hard, flat pavements (Fig. 16; e.g., see Pl. 49 in Petrie, 1917, and Fig. 6.31 in Arnold, 1991). Another tool thought to also assist in moving stone blocks is the so-called rocker. Made from wood, this device had two parallel, vertical sides that were joined by crossbeams as in the sledges (e.g., see Pl. 49 in Petrie, Fig. 89 in Clarke & Engelbach, 1930, and Fig. 6.29 in Arnold, 1991). The tops of the sides were flat and level, and their bottoms were rounded into a half circle or ellipse. There is much speculation on how the rockers were used, but it is generally agreed that a block of stone was placed on top of the sides, and then by rocking it back and forth, the block could be walked across a hard surface or pivoted to assist in its placement.

Extra: Wood or Iron Wedges?

In hard stone quarries dating to the latter part of the Late Period and especially the subsequent Greco-Roman periods, one sees lines of wedge-shaped holes on quarry faces and extracted blocks. It is a common misconception that these holes were cut to hold wedges of wood, which when wetted would swell and so split the rock along the line of wedge holes. In actuality, however, these holes were cut to hold iron wedges, which were struck with an iron sledgehammer to split the stone. This same method of splitting stone was also used in stone construction work toward the end of the Dynastic period.

Transporting Stone Money in Micronesia

Leslie C. Hazell

Institute of Latin American Studies, La Trobe University, Melbourne, VIC, Australia

The use of large stones or megaliths by ancient societies is often linked to construction or sculptures and associated cultural beliefs. But for one Micronesian society, stones were a form of currency. Known as stone money, or *rai*, Yapese society retrieved the limestone disks stones from Palau some 400 km away across open ocean waters, a process believed to have begun some 600 years ago. The stones varied considerably in size, with those moved in prehistoric times no larger than 2 m in diameter as determined by canoes of the time. A stone of this size would weigh over 2 t, but not all of the thousands moved were this big. Many men were involved in

the retrieval of these symbols of power, wealth, and status. In this role, the disks were used in transactions, including marriage gifts and debt repayment. Years could pass between quarrying

on Palau and the eventual return to Yap. This extended time also involved fulfilling obligations associated with acquiring the stone from the Palauans (Figs. 1 and 2).

Research often describes open sea voyaging and exploration, but the circumstances of the prehistoric Yapese stone transportation process are unique and not easily explained or understood before European influences changed the traditional methods and numbers of stones transported. However, the prehistoric retrieval is a fine example of navigation, seamanship, and the use of watercraft technology, including sails, sailing techniques, watercraft viability, and thus knowledge. It exemplifies skills and determination to acquire the stone. The returning crews were carrying a symbolic and prestigious, but destabilizing, cargo. To understand how difficult the acquisition of the stones was, maritime, canoe performance, and human physiology data as constraints are used to study the process known by Yap society through oral tradition and legend.

Transporting Stone Money in Micronesia, Fig. 2 Oceania region (Drawn by L. Hazell)

Geographic and Maritime Conditions

Yap and Palau form part of Micronesia, a Pacific region of some 3,000 islands occupying an ocean area of 7.4 million km². Yap is made up of four main islands, Yap, Gagil, Tomil, and Rumung, separated by narrow channels all surrounded by a fringing reef. The ocean expanse in which these remnants of volcanic action are situated is subject

to consistent wind patterns in particular the north-east trades. Their velocity is around 10 knots (18 km/h) during October through to May with a subtle variation in direction from northeast to east daily. Conditions such as these allow for 24 h sailing. In contrast, between July and October, only light winds occur, these being around 1.5 km/h. Ocean surface currents in particular the North Equatorial Current are also consistent

Transporting Stone Money in Micronesia, Fig. 3 (a) Prevailing winds: October to May, northeast trade winds (Sources: (Gatty, 1944; Morris & Rear Admiral, Hydrographer of the Navy, 1988; United States Navy [USN] 1995) Drawn by: L Hazell) (b) Ocean Surface Currents:

June to December, North equatorial current and equatorial counter current (Sources: (Gatty, 1944; Morris & Rear Admiral, Hydrographer of the Navy, 1988; USN 1995) Drawn by: L Hazell)

Transporting Stone Money in Micronesia,

Fig. 4 Tskupin sailing canoe and bamboo raft
(Drawn: L. Hazell)

between Yap and Palau, flowing west to east at around 1.25 knots or 2.5 km/h with a weaker NE set between August and October. There are variations to wind speeds and ocean currents noted in available records which would adversely laden craft (Fig. 3).

Open ocean conditions such as these determine the viability of ocean travel, particularly when undertaking the transportation of valuable loads. Meteorological and maritime data indicate these elements may hinder transport yet also provide power, if seasonal variations in conjunction with surface currents are taken into account. Analysis that includes human physiology and known watercraft and their performance has shown that this could be done.

Yapese Watercraft Performance and Power Options

Yap oral tradition and legends of prehistoric origin describe bamboo rafts and, more recent data notes, outrigger canoes used for fishing, with both configurations possessing different sailing properties. Bamboo is readily available and buoyant

as replication experiments and calculations show. A raft made up of this material would be capable of carrying the largest disks. However, due to the need for continuous paddling to make progress against prevailing currents, this method as a singular option seems unlikely. In addition the effective life of cut bamboo is short and subject to borer attack, a weakness critical when under load. The legends though state that the rafts were loaded and set adrift to then be towed back to Yap when found (Fig. 4).

Conversely sailing canoes were not capable of carrying the larger stones. For canoes, this is a question of buoyancy with sufficient freeboard needed to prevent passing waves filling the hull. Sufficient speed to equal wave speed generated by the winds found in the region is also linked to this limitation. Sailing configurations of either raft or outrigger canoe would need to be capable of tacking as a method to overcome the opposing winds and currents. In doing so, the total distance would not be 400 kms but over 1,100 kms thus imposing an endurance or survivability constraint on the crews. Not all would have survived the rigors of this extended voyage. Indeed, it is likely this mortality added value to the *rai*.

Transporting Stone Money in Micronesia,

Fig. 5 Tskupin configuration variant schematics: (a) Plan. (b) Side view. (c) Detail cross section (After Muller-Wisner in Haddon & Hornell, 1936–1938, p. 381 All drawings by Leslie C. Hazell)

Tacking was originally understood to be a Western sailing strategy, but a technique in this region, known as shunting, allows similar progress against the wind. This technique

relies on a number of structural elements, an asymmetrical hull shape, the beam-to-length ratio, and an outrigger for stability under sail. This format also allowed its use as a cargo

platform. The construction of this canoe was flexible, with variations to suit fishing or other needs of the time (Fig. 5).

The *tskupin* is a Yapese single-outrigger canoe with sail and cargo-carrying capability. Its effective sail configuration, superior freeboard, and speed potential are derived from other attributes that have lesser resistance compared to a raft. With those features, it is able to sail closer to the wind. In one example noted by de Beauclair (1963), this canoe configuration achieved an average speed of 2.0 knots or 3.7 km/h over five days and covered 470 km. The limitations of speed and seagoing capabilities of both raft and canoe configurations under load with the prevailing conditions if combined can explain the process described in legends. With laden bamboo rafts adrift, the faster yet light capacity sailing canoe could catch them up and tow the disk-laden rafts back to Yap (Müller, 1917).

This may seem as a dangerous practice with such valuable cargo, yet the speed and maneuverability of the outrigger canoe could make up the difference in a day, depending on raft drift rates which are affected by the size and mass of the disk or total load. Analysis of the process indicates that this would have been the most successful option nevertheless (Hazell & Fitzpatrick, 2006). The prehistoric undertaking contrasts the lost status and value of the *rai* brought about by European traders transporting large numbers of these disks with cargo ships as part of a trading exchange. Their size and limited numbers retrieved in prehistoric times also emphasizes Yapese seamanship and maritime knowledge and confirms Yapese oral traditions.

Trephination

Ruben G. Mendoza
Technology and Visualization, Institute for
Archaeological Science, California State
University, Monterey Bay, CA, USA

Perhaps one of the least understood surgical practices performed in ancient America concerns cranial trephination (also spelled “trepanation”), or the surgical modification of the skull. While much of the prevailing literature is largely dated, an older generation of theories tended to ascribe the practice to primitive wonderment and notions of spirit release and possession. This is despite a substantial body of technical evidence available from trephined specimens and a large and specialized body of surgical instruments and procedures documented in archaeological and contact-period historical contexts. According to medical historian Guido Majno, trephination was used as a cure for a number of ailments including skull fractures and related trauma, epileptic seizures, and insanity. In fact, many of those skulls examined to date bear evidence of blunt trauma or pathology that may provide a more direct indicator of why the practice was carried out in the first place.

While ancient Peru provides the largest body of trephined specimens available for study, and the clearest evidence of an established medical tradition in skull surgery, other important specimens have been reported from throughout the Americas. Documented examples, with evidence of osteitis, have been reported from the Mexican states of Chihuahua and Oaxaca, and archaeological sites in Lamy, New Mexico, and Accokeek, Maryland, in the United States, where trephined surgical openings are often no more than 2 cm in diameter. Reported trephined specimens from Columbia County, Georgia, archaeological zones along the Skeena River, and in the sites of Eburne and Lytton, British Columbia and Kodiak Island, Alaska, range between 3.8 and 6.0 cm in diameter. If all the putative cases of trephination reported in these examples are a reliable indication of areas in which the practice was known, then cranial trephination was quite widespread.

Majno has identified five primary techniques of trephination in specimens from both Peru and Mesoamerica. These include the most ancient method on record – the scraping-away of that bone just underlying the scalp – as well as other techniques such as grooving, boring, cutting, sawing, and rectangular intersection incision, the most predominant method employed, in which cut, sawed, or abraded grooves were used to perforate the skull in a rectangular pattern. Once the intersection incisions were connected to each other, a rectangular or octagonally shaped plate of bone remaining within the intersection was removed with a spatula-like device. Schendel (1968) notes that “the trepanning technique used in Mexico was to punch a series of small holes in the skull outlining the fracture, or the area to be removed, then to cut between those holes and lift off the depressed section of cranial bone.” After this initial procedure, the exposed brain was protected with a thin plate of hardwood and cotton pads. When trephination was not deemed suitable because of the extent of skull trauma, the damaged portion of skull was encased in a protective plaster cast. There were two types of plaster cast. The first was a mixture of feathers, egg whites, and resin, and the second was

prepared from a mixture of animal ash, blood, and egg whites.

Specialized tools and instruments employed by Inca physicians in the trephination of the skull included *tumi* knives crafted from alloyed and annealed, or metalurgically hardened, copper and bronze metals. The *tumi* knife consisted of a crescent-shaped blade, at the midpoint of which was attached a cylindrical metal handle or other appendage. *Tumi* knives used in trephination included razor sharp, serrated, or other saw-tooth-edged crescent-shaped scalpels. Additional instruments included bronze perforators, drills, and chisels. The basic surgical instrumentation utilized in cranial trephination long predated the rise of the Inca state, whose government came to sponsor and control this specialized field of medical endeavor (Burland, 1967). Cranial trephination, and both *tumi* knives and bronze perforators, are frequently depicted on the carved and painted surfaces of vessels of the Mochica civilization of the north coast of Peru (ca. AD 500).

In one collection of 273 skulls from Peru, 47 bore evidence of having been trephined between one and five times. According to Majno, the skulls studied thus far suggest that the survival rate was near 100 %. Only a few cases of osteomyelitis, or bone deterioration, were documented in the cranial collection he examined. Those cases appear to have been associated primarily with the size of the original injury, and whether or not the trauma was located at the base of the skull. Apparently, patients suffering blunt trauma over the cerebral cortex or brain stem were least likely to benefit from treatment by trephination. In other recent studies, projected survival rates, based on the examination of the presence of osteitis, range from 62.5 % in one study that found healing or evidence of osteitis in 250 of 400 skulls examined, to between 23.4 % and 55.3 % in other studies (Froeschner, 1992). These latter figures are questionable in that the studies cited by Froeschner do not distinguish postmortem trephination from that performed on severely traumatized patients. Froeschner's review also fails to acknowledge the existence of even the most basic metal instruments and surgical kits documented for the

practice of trephination in ancient Peru, claiming instead that "primitive tools" were the mainstay of the art of Inca trephining.

It is clear that specialized techniques and treatments contributed to the diversity and variation in surgical localities known from trephined specimens alone. In one analysis of a trephined skull collection consisting of 112 specimens (the Tello collection housed at the Peabody Museum of Harvard), 53.6 % of the skulls, or 60 specimens, bore trephined areas in the frontal area of the skull (26 of which were situated in the frontal bone, 12 in the region of the bregma, and another 12 crossing over the left coronal suture); 33 %, or 37 specimens, were trephined in the parietal area (18 of which bore surgical openings over the left parietal, while 15 crossed the sagittal suture), and 13.4 %, or 15 specimens, were trephined over the occipital area (with 7 in the region of the lambda, and 4 in the occipital bone). Most trephined specimens from the Harvard collection bear surgical openings within the frontal areas of the cranium, and again, trephined openings are most highly correlated with blunt trauma and other pathologies. The incidence of epileptic seizures among Inca era peoples was documented by both European-contact chroniclers and contact-era Inca scribes. This fact may provide directions for future inquiry into the origins of specific types of trephination among Inca and related peoples.

Based on a worldwide survey of ancient skull surgery, Majno has concluded that the Inca were the "Masters of the Art of Trepanning." He also noted that the survival rate for patients in Inca times was better than for such rates in modern times. He says that modern survival rates are the inverse of what they had been in earlier Inca times, and concludes that modern humans complicated the task of skull surgery by introducing new sources of infection and disease. In turn, modern physicians were trained to perpetuate otherwise antiquated traditions of skull surgery based on flawed nineteenth century assumptions and beliefs. European medical belief systems regarding infection, surgical procedure, anesthetics, and basic hygiene necessitated a constantly expanding and contracting repertoire of

experimental procedures which further complicated survival rates. As a result, the fledgling early twentieth century version of modern skull surgery suffered many casualties.

Tribology

Lu Jing-Yan

Tribology, the study of the phenomena and mechanisms of friction, lubrication, and wear of surfaces in relative motion, can be traced back to remote antiquity in China, where it developed significantly.

Sliding bearings were discovered in ancient mechanisms, especially in carts which operated at high speeds and carried great loads. In order to reduce friction and damage, Chinese mechanics lubricated bearings on their carts. This was recorded in the earliest poetry collection entitled *Bei Fen Quan Shu* (The Bei Wind and Spring Water) as follows:

- *The grease used is sufficient to lubricate the axle shaft.*
- *On the shaft end, we carefully check the pin bolt.*
- *Quickly, send me home driving the cart.*
- *Quickly, send me back to my Wei country town.*

It proves that before the book *Shi Jing* (Poems and Odes) appeared – before 1100–600 B.C. E. – lubricant was widely applied in China. Owing to their rhythmic quality, the verses were repeatedly quoted and talked about, and often appeared in later books as well.

By the time of the Chun Qui (Spring-Autumn) period (500 B.C.E.) in the Lu and Qi states, there was a group of special officers called *Jinche*,

whose duty was to check the pin bolts on the shaft ends. They were probably the earliest tribology supervisors. This demonstrates that the ancient Chinese already knew well that the better the lubrication, the faster and easier ran the cart.

Early lubricant was called *zhi* or *gao*. According to research on ancient characters, *zhi* was the fat of horned animals, and that of hornless animals was called *gao*. The lubricant used might be sheep oil, which was easier to get. Since *zhi* or *gao* is in a solid state at normal temperature, it had to be heated and melted before it was used. In 300 B.C.E. petroleum began to be used.

Metal bushes appeared in China quite early. There were relevant records about their use in *Wuzi Yebing* (Wuzi casting), which shows that they appeared not later than 400 B.C.E. The metal bush was made of two layers: outside and inside. The outer one was called *gong*, which turned together with the wheel, and the inside one was *jian*, which turned together with the shaft. Between them a kind of lubricant was provided, and the cart ran quickly and easily. In addition to carts, the metal bushes were applied in other mechanisms of antiquity, and they appeared in a variety of forms. In the Han Dynasty, they were already used quite widely. This is illustrated by the discovery of hundreds of mold sets of metal bushes in county Wen in Henan province. Most of them were still undamaged. They reflect the level of manufacturing as well as the scale of their production and application in the Han Dynasty.

The ancients took other measures to reduce friction and damage. Most mechanisms were made of wood. In the *Kao Gongji* (The Artificer's Record), three principles of wood selection were listed (1) the wood must be smooth, without joints; (2) it must be tough and wear-resistant; and (3) it must be thick enough and easy to revolve. In the sixteenth century a book entitled *Tian Gong Kaiwu* (Exploitation of the Works of Nature) was written, in which a further summary on the basis of experience was made. It analyzed the advantages and shortcomings of various woods, and provided an example: if wood works for too long, it gives out heat. In the field of structural design, the *Kao Gongji* and other books analyzed the relationship between the

axis path and the length of the shaft, and pointed out that when the cart and load were different, the interior axis of the wheel must keep a fixed proportion to the length of the shaft.

There was one other achievement of note in this field. In the Yuan Dynasty (thirteenth century) a ball bearing, which was circle-formed and consisted of four balls, was successfully applied to an astronomical instrument made by Guo Shoujing.

Trigonometry in Indian Mathematics

Michio Yano

Faculty of Cultural Studies, Kyoto Sangyo University, Kyoto, Japan

Trigonometry offers one of the most remarkable examples of transmission of the exact sciences in antiquity and the Middle Ages. Originating in Greece, it was transmitted to India and, with several modifications, passed into the Islamic world. After further development it found its way to medieval Europe.

The very term “sine” illustrates the process of transmission. The Greek word for “chord” ($\epsilon\upsilon\theta\epsilon\iota\alpha$, literally “a straight line [subtending an arc]”) was translated into Sanskrit as *jīva* or *jyā* (“string of a bow”) from the similarity of its appearance. The former word was phonetically translated into Arabic as *jyb*, which was vocalized as *jayb* (meaning “fold” in Arabic), and this was again translated into Latin as *sinus*, an equivalent to the English sine.

It was by tracking back along this stream of transmission that the first chord table ascribed to Hipparchus (fl. 150 BCE) was recovered by Toomer (1973) from an Indian sine table (compare Tables 1 and 2). Toomer showed that some numerical values ascribed to Hipparchus in the *Almagest* of Ptolemy (fl. AD 150) could be explained by hypothesizing the use of this reconstructed table.

According to this reconstruction, Hipparchus used 6,875' as the length of the diameter (D) of the base circle, in other words, as the greatest

Trigonometry in Indian Mathematics, Table 1 Hipparchus' chord table reconstructed

Number	α	$R \text{ crd } \alpha$

20	150	6,641
21	157; 30	6,743
22	165	6,817
23	172; 30	6,861
24	180	6,875

chord subtending the half circle ($=R \text{ crd } 180^\circ = 6,875$). This number is the result of rounding after dividing $21,600'$ (360°) by the value of $\pi = 3; 8, 30$. (In this article we follow the convention: integer and fraction are separated by a semicolon, the former is in decimal form, and the latter is in sexagesimal form with commas to separate the places.) In India $3,438'$, namely, the rounded half of D , was used as the length of the radius (R), which is the largest "half chord" (*jyārdha* or *ardhajyā*).

Thus the relation between the Greek chord and the Indian sine can be expressed as

$$AB = 2AH, R \text{ crd } 2\alpha = 2R \sin \alpha. \quad (1)$$

Plane trigonometry was the essential tool for mathematical astronomy in India. All the astronomical texts in Sanskrit either give a kind of sine table or presuppose one. On the other hand, trigonometry was studied only as a part of astronomy

Trigonometry in Indian Mathematics, Table 2 Indian sine table with $R = 3,438$

24	90	3,438	7

and it was never an independent subject of mathematics. Furthermore, since they were not aware of spherical trigonometry, Indian astronomers developed the method called *chedyaka* in which the sphere was projected on to a plane.

Sine Table with $R = 3,438$

The earliest Indian sine table with $R = 3,438$ is found in Āryabhaṭa's book on astronomy, *Āryabhaṭīya* (around AD 500). It should be remembered that "table" here does not mean that the numbers are actually arranged in a tabular form, i.e., in lines and columns. As is usually the case with Sanskrit scientific texts, all the numbers are expressed verbally in verse. For brevity's sake, Āryabhaṭa gives only the tabular differences (Δ , the fourth column of Table 2). This is the standard sine table in ancient India.

Exactly the same table is found in the *jiuzhili*, a Chinese text on the Indian calendar written in AD 718 by an astronomer of Indian descent, but it did not have any influence on Chinese mathematics.

The values of sines were geometrically derived from $R \sin 90^\circ (=R)$ and $R \sin 30^\circ (=1/2 R)$ by two formulas:

$$R \sin (90^\circ - \alpha) = \sqrt{R^2 - (R \sin \alpha)^2}, \quad (2)$$

$$R \sin \frac{\alpha}{2} = \sqrt{\left\{ \frac{R - R \sin (90^\circ - \alpha)}{2} \right\}^2 + \left(\frac{R \sin \alpha}{2} \right)^2}. \quad (3)$$

It is worth noting here that the first tabular sine was equated with the arc $(3; 45^\circ = 225')$ which it subtends. This means that, when α' is small enough, the approximation $\sin \alpha' \approx \alpha'$ can be applied.

What is more remarkable in Āryabhaṭa is that he gives an alternative method for computing tabular differences by means of the formula:

$$\Delta_{n+1} = \Delta_n - (\Delta_1 - \Delta_2) \frac{J_n}{J_1},$$

where $J_n = R \sin n(3; 45^\circ)$. The formula, after several centuries of misunderstanding, was correctly interpreted by a South Indian astronomer Nīlakaṇṭha (born in 1444), one of the most distinguished scholars belonging to the Mādhava school (see below). When suitable values of $(\Delta_1 - \Delta_2)$ and J_1 are used, this formula produces very good values for the rest of R sines. It seems that Āryabhaṭa's sine values were computed by this second method rather than by the geometrical method. This means that the table with $R = 3,438$ is not a mere copy of the Hipparchan table, if ever existed.

Sine Table with $R = 120$

There is another kind of Indian sine table which uses $R = 120$. The table is found in the

Trigonometry in Indian Mathematics, Table 3 Comparison of the first four and last four values in the *Pañcasiddhāntikā* with those of Ptolemy

Number	α ($^\circ$)	Varāhamihira with $R = 120$	Ptolemy with $R = 60$
		$R \sin \alpha$	$R \text{ crd } 2\alpha$
1	3; 45	7; 51	7; 50, 54
2	7; 30	15; 40	15; 39, 47
3	11; 15	23; 25	23; 24, 39
4	15	31; 4	31; 3, 30
...	...	...	...
21	78; 45	117; 42	117; 41, 40
22	82; 30	118; 59	118; 58, 25
23	86; 15	119; 44	119; 44, 36
24	90	120	120

Pañcasiddhāntikā of Varāhamihira, a younger contemporary of Āryabhaṭa. This table is closely related to the Greek chord table with $R = 60$ which is offered in Ptolemy's *Almagest*. Because of the relation (1) given above, all the numerical values in the chord table with $R = 60$ can be transferred directly to the sine table with $R = 120$. Table 3 compares the first four and the last four values in the *Pañcasiddhāntikā* with Ptolemy's corresponding ones. The fractional parts after the semicolon in both tables are expressed sexagesimally. It seems that Varāhamihira's values were the results of rounding the numbers in the second fractional place of a chord table similar to that of Ptolemy.

In these earlier Indian sine tables, only the 24 values in the first quadrant are given, with the interval of $3^\circ 45'$. Although Indians knew and used cosines (*koṭijyā*), they had no need of tabulating them because they knew that cosines could be derived from sines by the relation (2) above. On the other hand, they were interested in the versed sine (*śara* in Sanskrit, meaning "arrow" or *utkramajyā*, "sine of the reversed order," CH in Fig. 1) which is defined as

$$\sin \theta = \theta - \frac{\theta^3}{3!} + \frac{\theta^5}{5!} - \frac{\theta^7}{7!} + \frac{\theta^9}{9!} - \dots$$

Using this relation, Brahmagupta (seventh century) simplified some formulas. For instance, formula (3) was rewritten as

Trigonometry in Indian Mathematics,

Fig. 1 Sine of the reversed order

$$R \sin \frac{\alpha}{2} = \sqrt{\frac{D \times R \text{ vers } \alpha}{4}}. \quad (3)$$

A table of versed sines can be easily obtained by adding Δs in Table 2 successively from the bottom upward (namely, in the “reversed order”).

Brahmagupta computed anew 24 sines with $R = 3,270$ in the *Brāhmasphuṭasiddhānta*. Elsewhere in this book and in the *Khaṇḍakhādya*, he offers a sine table with $R = 150$ and with the interval of 15° . This small table generates remarkably correct sine values when his ingenious method of second order interpolation is applied.

Bhāskara II

An improved version of the traditional sine table was prepared by Bhāskara II (b. 1114). In the chapter “Derivation of Sines” (*Jyotpatti*) of his *Siddhāntaśiromaṇi*, he introduces two new values:

$$R \sin 36^\circ = \sqrt{\frac{5 - \sqrt{5}}{8}} R,$$

$$R \sin 18^\circ = \sqrt{\frac{\sqrt{5} - 1}{4}} R.$$

With these two values and formulas (2) and (3) above, he obtains $R \sin 3n^\circ$ (where $n = 1, 2, 3, \dots, 30$). Further he combines them with the approximate value

$$R \sin 1^\circ \approx 60'$$

using the new formula

Trigonometry in Indian Mathematics, Table 4 Mādhava’s sine table

Number	α ($^\circ$)	$R \sin \alpha$
1	3; 45	0224; 50, 22

22	82; 30	3,408; 20, 11
23	86; 15	3,430; 23, 11
24	90	3,437; 44, 48

$$R \sin (\alpha \pm \beta) = \frac{R \sin \alpha R \cos \beta \pm R \cos \alpha R \sin \beta}{R}, \quad (4)$$

which is equivalent to the modern formula:

$$\sin (\alpha \pm \beta) = \sin \alpha \cos \beta \pm \cos \alpha \sin \beta.$$

Thus he could obtain sines for all the integer degrees of a quadrant. Formula (4) was unknown to Indians before Bhāskara II, while a chord version of the same formula was known to Ptolemy.

Trigonometry underwent a remarkable development in the early fifteenth century on the western coast of South India (the modern state of Kerala). The person who initiated this development was Mādhava (fl. ca. 1380/1420) of Saṅgamagrāma (near modern Cochin). His important works on astronomy and mathematics are now lost, but we know his achievements from the books of his successors. A sine table ascribed to him is quoted in

Nīlakaṇṭha's commentary on the *Āryabhaṭīya* (Table 4).

A couple of verses, which are often quoted by the students of the Mādhava school and which are ascribed to Mādhava himself by Nīlakaṇṭha, give the method of computing sines. The method can be expressed as

$$R \sin \theta = \theta - \frac{\theta^3}{3!R^2} + \frac{\theta^5}{5!R^4} - \frac{\theta^7}{7!R^6} + \frac{\theta^9}{9!R^8} - \dots$$

with $R = 1$ this is equivalent to Newton's

$$\sin \theta = \theta - \frac{\theta^3}{3!} + \frac{\theta^5}{5!} - \frac{\theta^7}{7!} + \frac{\theta^9}{9!} - \dots$$

Similar power series for cosine and versed sine are ascribed to Mādhava.

Trigonometry in Islamic Mathematics

Boris A. Rosenfeld
PA, USA

Trigonometry is the connecting link between mathematics and astronomy, between the way calendars are calculated, the gnomon, and the sundial. In the Islamic world, the calculation of spherical triangles was necessary to carry out ritual customs. The *qibla*, the direction to Mecca, was indicated next to the hour lines on all public sundials.

The first trigonometric problems appeared in the field of spherical astronomy. Around the year 773, one of the Indian *siddhāntas* (astronomy books) was made known in Baghdad. The Indian astronomers Varāhamihira (fifth century) and Brahmagupta (sixth century) solved different problems in spherical astronomy by means of rules equivalent to a general sine theorem for a spherical triangle ABC with sides a, b, c and angles A, B, C (where angle A is opposite to side a , etc.), namely, $(\sin A / \sin a) = (\sin B / \sin b) = (\sin C / \sin c)$ and to the cosine theorem for the same triangle $\cos a = \cos b \cos c + \sin b \sin c \cos A$.

In the ninth century, Ptolemy's *Almagest* and Menelaus' *Spherics* were also translated, and commentaries were written to these works. Many trigonometric problems were solved in Ptolemy's *Almagest*, in which Menelaus' theorem on the spherical complete quadrilateral was used. The cases of this theorem used by Ptolemy are equivalent to the sine and tangent theorems for a right-angled spherical triangle. The *Almagest*, the *Spherics*, and the Indian *siddhāntas* formed the basis on which Arab mathematicians built their trigonometry.

The ancient Greek astronomers only used one trigonometric function, the chord of an arc. The "theorem of Ptolemy," which is equivalent to the formula for the sine of the sum of the angles, forms, together with the formula for the chord

of the half arc, the basis for the chord table in the *Almagest*. The Indian people replaced the chord with the sine, introduced the cosine and the versed sine, and compiled a small table of sine values. The Arabic mathematicians progressively made trigonometry into a science independent of its (astronomical) context.

Applications of trigonometry analogous to those in the Indian *siddhāntas* are found in the astronomical works of al-Khwārizmī. An analogous geometric construction for finding the azimuth according to the rule formulated in al-Khwārizmī's third treatise was provided by al-Māhānī (ca. 825–888) in his *Treatise on the Determination of the Azimuth at Any Time and in Any Place*. The rules equivalent to the spherical sine and cosine theorems were also used by Thābit ibn Qurra in his *Book on Horary Instruments Called Sundials*. With Ḥabash, the applications of the tangent and cotangent functions went beyond the usual applications in the theory of sundials. The introduction of the tangent and cotangent and their application in astronomy was a novelty. The names *zill* (shadow) and *zill ma'qus* (reversed shadow) apparently are translations from Sanskrit. In the case of a vertical gnomon, al-Ḥabash expressed the cosecant as the “diameter of the shadow” for a given height of the sun, i.e., as a hypotenuse. He computed a table for the cosecant with steps of 1° .

For a long time, the chord was used along with the sine. A theory of these magnitudes is found in the work of al-Battānī (ca. 858–929). In his astronomical work *Islāḥ al-Majisī* (The Perfection of the *Almagest*), he systematically employed the trigonometric functions sine and versed sine with arguments between 0° and 180° . Since the cosine is defined as the sine of the complement of the angle and since no negative numbers are used, the versed sine is defined in the second quadrant as a sum of two quantities. The elements of trigonometry are set forth in an even more systematic way in the *Kitāb al-Kāmil* (Perfect Book) of Abū'l-Wafā' (940–997/998). He defined several trigonometric functions in the circle with radius 1. The trigonometric tangent function is defined as a line on a tangent to the circle.

The proof of the general spherical sine theorem was given by Abū'l-Wafā' in his *al-Majisī* (*Almagest*), by his pupil Abū Naṣr ibn 'Irāq (d. 1036) in the *Risāla fī ma'rifa al-qisī al-falakiyya* (Treatise on the Determination of Celestial Arcs), and by al-Khujandī (d. ca. 1000) in the *Kitāb fī al-sā'āt al-māḍiyya fī al-layl* (Book on Past Hours in the Night). The history of the discovery of this theorem was described by al-Bīrūnī, the pupil of Ibn 'Irāq and al-Khujandī, in the *Kitāb maqālīd 'ilm al-hay'a* (Book on the Keys of Astronomy).

The use of trigonometry was expanded through al-Bīrūnī (973–1048). He is the author of the *Mas'ūdic Canon*, which is a summary of the results from the works of many predecessors and of personal observations and calculations. It comprises 11 books. Book 3 is dedicated to trigonometry. It has calculations equivalent to the formulas for the sine of the sum of two angles, the sine of the differences between two angles, and the sine of the double angle. It also includes the solution of cubic equations and the division of angles into three parts and the sine rule of plane trigonometry: $(\sin A/a) = (\sin B/b) = (\sin C/c)$. (The plane cosine theorem $a^2 = b^2 + c^2 - 2bc \cos A$ is equivalent to two of Euclid's theorems.)

Another important scholar in the area of trigonometry was Naṣīr al-Dīn al-Ṭūsī (1201–1274). His principal work was *Kitāb al-shakl al-qattā'* (Book on the Secant Figure, also known as *Treatise on the Complete Quadrilateral*). It was written in Persian and translated by the author into Arabic in 1260 possibly for the needs of the observatory of Maragha. In five books, it contains a full system of trigonometric formulas for plane and spherical triangles. If any three elements of such a triangle are given, the other three elements can be found by the theory explained in this work, which also contains the notion of the polar triangle $A'B'C'$ of a spherical triangle ABC ($A' = 180^\circ - a$, $B' = 180^\circ - b$, $C' = 180^\circ - c$). This work played an important role in the development of mathematics in Europe.

U

Ulugh Bēg

Boris A. Rosenfeld
PA, USA

Ulugh Bēg, Mīrzā Muḥammad ibn Shāhrūkh ibn Tīmūr Ulugh Bēg Guragān, 1394–1449, was the ruler of Samarqand (now in Uzbekistan) and an astronomer, mathematician, and poet. His nickname, Ulugh Bēg, means “great prince.” He was the grandson of the great conqueror Tīmūr. In 1417, as a pupil of Qādī Zādeh al-Rūmī of Bursa (Turkey), he opened in Samarqand the *madrassa* (school) where al-Rūmī was the teacher. In 1425, he founded an astronomical observatory and invited Jamshīd al-Kāshī to be its director. After al-Kāshī’s death, the head of the observatory became ‘Alī al-Qūshjī. Ulugh Bēg was killed by enemies of enlightenment. After his death, his observatory was destroyed, and al-Qūshjī fled to Turkey.

The main work of Ulugh Bēg was a book of astronomical tables known as the *Zīj-i Ulugh Bēg* or *Zīj-i jadīd-i Guragānī* (New Zīj of Guragan) written together with al-Kāshī, al-Rūmī, and al-Qūshjī. The tables are written in Persian and are extant in many manuscripts in Persian and Arabic translations. The work consists of four books of

trigonometrical, astronomical, geographical, and astrological tables.

Book I covered the subject of calendars, including the Muslim lunar calendar, the pre-Islamic Persian solar calendar, and the Chinese-Uyghur calendar. Book II dealt with spherical astronomy, covering sine and versed sine, shadows (tangents and cotangents), spherical coordinates on the celestial sphere (equatorial, ecliptical, and horizontal coordinates), geographical coordinates, as well as spherical distances between stars and the direction of *qibla* (to Mecca). In Book III Ulugh Bēg considered planetary and stellar astronomy, such as the motion of the sun, moon, and planets, the distances of the sun and the moon from the center of the world, and the equalization of astrological houses. Finally, Book IV dealt with astronomical calculations.

Ulugh Bēg also was the author of the mathematical *Risāla fī istikhrāj jayb daraja wāhida* (Treatise on the Determination of Sine of One Degree). Originally the treatise was wrongly ascribed to al-Rūmī; Ulugh Bēg’s authorship was established on the basis of the information in al-Bīrjandī’s commentaries to the *Zīj* of Ulugh Bēg.

Umar al-Khayyām

Boris A. Rosenfeld
PA, USA

‘Umar al-Khayyām (Ghiyāth al-Dīn Abū’l-Faṭḥ ‘Umar ibn Ibrāhīm Khayyām (al-Khayyāmmī) al-Naysābūrī (Nīshāpurī), 1048–1131) was a Persian mathematician, astronomer, philosopher, and poet. His scientific treatises were written primarily in Arabic; his poems were mostly written in Persian. The name Khayyām means “the tentmaker” – probably it was the profession of his father or grandfather. He was born and died in Nīshāpūr. Khayyām was a student in Balkh (now in Afghanistan) and worked at first in Bukhārā and Samarqand (now in Uzbekistan). In 1074 he was invited by Saljūq Sultan Mālikshāh Jalāl al-Dīn to the capital Iṣfahān to participate in the reform of the solar Persian calendar and to organize an astronomical observatory. The calendar reform was completed in 1079; the new calendar era was named according to the names of the sultan Māliki or Jalālī. In 1092, after Mālikshāh’s death, Khayyām fell into disgrace, and his observatory was closed. This was because of suspicions that some of his verses were anti-Islamic. To allay these suspicions, he made a pilgrimage to Mecca. Later he worked in Marw (now Marv in Turkmenistan) which was the new capital of the Saljūq sultans.

Two of Khayyām’s treatises are very important for the history of mathematics. One is the *Risāla fī’l-barāhīn ‘ala masā’il al-jabr wa’l-muqābala* (Treatise of Demonstrations of Problems of Algebra), written in Samarqand and dedicated to the judge Abū Ṭāhīr who had given him the opportunity to devote himself to the science. The topic of this work was the theory of cubic equations. Here the complete classification of cubic equations with positive roots was given, and for every type of equation, the solution by means of the intersection of circumferences,

Boris A. Rosenfeld: deceased

equilateral hyperbolas, and parabolas was also given.

The second work is the *Sharḥ mā ashkala min muṣādarāt kitāb Uqlīdis* (Commentaries on Difficulties in Introductions of Euclid's book). It was written in Iṣfahān in 1077 and contains the commentaries to Euclid's *Elements*. The treatise consists of three *maqālas*: (1) on the theory of parallels, (2) on the theory of ratios, and (3) on the theory of compound ratios. The ideas of this work were developed further by Naṣīr al-Dīn al-ṭūsī (1201–1274), John Wallis (1616–1703), and Girolamo Saccheri (1667–1733) (Khayyām's quadrangle is also called Saccheri's quadrangle).

Before the *Risāla fī'l-barāhīn*, Khayyām wrote the *Risāla fī taqṣīm rub' al-dā'ira* (Treatise on Division of a Quarter of a Circle) and *Mushkilāt al-ḥisāb* (Problems of Arithmetic). In the first, a geometric problem is considered. It is reduced to a cubic equation whose solution by means of the intersection of the circumference and equilateral hyperbola and an approximate numerical solution are found. Here the problem of classifications of cubic equations is formulated. The second work is not extant but is mentioned in the former as "the treatise on the demonstration of methods of Indians of extraction of square and cube roots and on generalization of these methods for determination of bases of square-squares, square-cubes, cube-cubes and so on as many as you like, what was not earlier." These words show that this work was devoted to the extraction of roots of n th degree, which was explained later in the arithmetic treatise of Naṣīr al-Dīn al-ṭūsī. Probably in this work, as in al-ṭūsī's treatise, "Newton's binomial formula" for $(a + b)^n$ for an arbitrary natural n was explained.

Khayyām also made many contributions to the study of astronomy and the calendar. His *al-Zīj Mālikshāhī* (Malikshah Astronomical Tables) is not extant, except for the catalog of fixed stars from this work. In Khayyām's calendar, there were eight intercalary days in 33 years. The error is 1 day in 5,000 years (in the Gregorian calendar, the error is 1 day in 3,330 years). After the closing of his observatory, Khayyām wrote the Persian historical treatise *Nowrūz-nāmeḥ*

(Book on the New Year) on reforms of the solar Persian calendar and on the Persian New Year holiday Nowrūz in pre-Islamic Iran.

In the field of physics, Khayyām wrote *Fī ikhtiyāl ma'rifa miqdāray al-dhahab wa'l-fidḍa fī jism murakkab minhumā* (On the Art of Determination of Quantities of Gold and Silver in a Body Consisting of Them) and *Fī'l-quṣṭāṣ al-mustaqīm* (On the Right Balance). Both of these works are included in the *Kitāb mīzān al-ḥikma* (Book of the Balance of Wisdom) of Khayyām's student 'Abd al-Raḥmān al-Khāzinī, who worked in Marv. In this he explains a method to determine specific gravity.

Khayyām also made significant contributions to music and philosophy. He wrote a *Qaul 'alā ajnās allatī bi'l-arba'a* (Speech on Genera Which are [formed] by a Quarter) on the division of a quarter into three intervals in accordance with three genera of tonality – diatonic, chromatic, and enharmonic.

In philosophy, Khayyām was a follower of Aristotle and Ibn Sīnā (Avicenna). On the question of universalia, he was near to Peter Abelard. Many philosophical questions were considered in Khayyām's poetry, particularly in his well-known *Rubā'īyāt* (Quatrains).

Vāgbhaṭa

Guy Mazars

In the history of medicine in India, Vāgbhaṭa is the most celebrated author after ► [Caraka](#) and ► [Suśruta](#). It is not known at what period Vāgbhaṭa lived. We usually place him in the sixth century; he is in any case earlier than the tenth century. His identity has been the subject of unending discussion, and Indian critics hold that there was an “elder Vāgbhaṭa” in addition to “Vāgbhaṭa”, grandson of the former and son of Siṃhagupta.

Several treatises of Āyurveda (Indian medicine; see article in the encyclopaedia) are ascribed to him. The most interesting are the *Aṣṭāṅgasamgraha* and the *Aṣṭāṅgahṛdayasaṃhitā* which are probably two different versions of the same medical text whose teachings agree generally with those of Caraka and Suśruta. However the more commonly used text of Vāgbhaṭa is the *Aṣṭāṅgahṛdayasaṃhitā* or “Compendium on the Heart of Medicine” which is considered the greatest synthesis on Āyurveda ever produced. The Chinese pilgrim Yi Jing, who stayed in India from AD 673 to 688, spoke, without mentioning its name, of a work that was then recent and that summarised the eight branches of medicine. It is thought that he was referring to the work of Vāgbhaṭa, but he may also have been referring to

the *Yogaśataka*, “The Hundred Formulas”, which fits Yi Jing’s description perfectly. This work consists, as its name indicates, of a series of 100 therapeutic formulas distributed according to the eight theoretical divisions of Āyurveda. Its author is a certain Nāgārjuna, perhaps the same author who is reputed to have revised the *Suśrutasaṃhitā* but who is not necessarily the Buddhist patriarch of that name with whom he is nevertheless identified by the tradition.

The *Aṣṭāṅgahṛdayasaṃhitā* gives full expression to the richness and detail of the ancient tradition of Āyurveda. Numerous manuscripts of the work are extant in Indian libraries and the first printed edition appeared in 1874–1878 in Calicut. Since then, countless editions of the whole or of parts of the treatise have been published.

Vāgbhaṭa enjoyed early and widespread recognition. The *Aṣṭāṅgahṛdayasaṃhitā* was the object of numerous commentaries. The work is quoted in the *Firḍaws al-Ḥikma* or “Paradise of Wisdom” composed in AD 850 by the Persian physician ‘Alī ► [Ibn Sahl](#) Rabban aṭ-Ṭabarī who gives a very complete summary of the āyurvedic doctrines. The *Aṣṭāṅgahṛdayasaṃhitā* was also translated into Tibetan and incorporated into the immense Buddhist Encyclopaedia of the *Tanjur* between the years 1013 and 1055.

Vākyakaraṇa

K. V. Sarma
Madras, Tamilnadu, India

Vākyakaraṇa, apocryphally ascribed to Vararuci, is an astronomical manual produced in about AD 1300 which was very popular in South India, especially in Tamil Nadu and the adjoining regions. The work is so called because it was a *karaṇa* (astronomical manual) which used computational tables where the numbers are expressed in mnemonic sentences (*vākyas*), phrases, and words. It is also called *Vākyapañcādhyāyī*, because it contains *pañca adhyāyas* (five chapters). Until recently, when

the *Nautical Almanac* came to be used in South India for the computation of the Hindu almanac with its “five limbs” (*pañcaṅga*): the lunar day, weekday, asterism, *yoga*, and *karaṇa*, the *Vākyakaraṇa* was widely used for that purpose.

The author of the *Vākyakaraṇa* hailed from Kariśaila or Kāñchī in Tamil Nadu, as he himself states in his work. He also states that he based his work on the writings of Bhāskara I (AD 629), the exponent of the school of astronomy promulgated by Āryabhaṭa (b. AD 476), and the works of Haridatta (AD 683), author of *Grahacāranibandhana* and *Mahāmārganibandhana*. The *Vākyakaraṇa* was elaborately expounded by Śundararāja (AD 1500), who had contacts with the Kerala astronomer Nīlakaṇṭha Śomayāji. The date of *Vākyakaraṇa* is determined as ca. AD 1300, on the basis of epochs which the author gives for the computation of the planets.

In five chapters, the *Vākyakaraṇa* deals with all aspects of astronomy required for the preparation of the Hindu almanac. Chapter I is concerned with the computation of the sun, the moon, and the moon's nodes and Chapter II with that of the planets. Chapter III is devoted to problems involving time, position, and direction and other preliminaries like the precession of the equinoxes. The computation of the lunar and solar eclipses is the concern of Chapter IV. Chapter V is devoted to the computation of the conjunction of the planets and of planets and stars.

For the computation of the moon, the *Vākyakaraṇa* employs the 248 moon sentences of the ancient astronomer Vararuci. But for the five planets Mars, Mercury, Jupiter, Venus, and Saturn, the author himself computed 82 tables devoted to the different planetary cycles, containing, in all, 2,075 mnemonic sentences (*Kujādi-pañca-graha-mahāvākyas*).

The results obtained through the computations enunciated in the *Vākyakaraṇa* are not very accurate, going by modern standards, but they were accurate enough for the determination of auspicious times and other matters required in the routine life of orthodox Hindus. Besides, there

was the saving of much time and labor in working with the simple methods advocated in the work.

Values and Science

Ziauddin Sardar

Is science value free? If “science,” as Lord Ruth-erford is reported to have said, “is what scientists do” then scientists would have to be superhuman to keep their values out of what they do in their laboratories. We cannot clinically isolate our cultural and ethical (and through them our historical) baggage from our human activities. Values play an important part in what we select to do or not do and how we actually do it. In as far as science is a human activity, it is subject to the strengths and weaknesses of all human activities.

However, in Western tradition, up to quite recently, scientists were seen as quasireligious supermen, heroically battling against all odds to

discover the truth. Also, the truths they wrestled out of nature were said to be absolute, objective, value-free, and universal. The idea of scientists as dedicated hermit-like lone researchers is now obsolete. Nowadays, science is an organized, institutionalized, and industrialized venture. The days when individual scientists, working on their own, and often in their garden sheds, made original discoveries are really history. Virtually all science today is big science requiring huge funding, large, sophisticated, and expensive equipment, and hundreds of scientists working on minute problems. As such, science has become a unified system of research and application, with funding at one end and the end-product of science, often technology, at the other.

Values enter this system in a number of ways. The first point of entry is the selection of the problem to be investigated. The choice of the problem, who makes the choice and on what grounds, is the principle point of influence of society, political realities of power, prejudice, and value systems on even the “purest” science. Often, it is the source of funding that defines what problem is to be investigated. If the funding is coming from government sources then it will reflect the priorities of the government – whether space exploration is more important than health problems of the inner city poor, or nuclear power or solar energy should be developed further. Private sector funding, mainly from multinationals, is naturally geared toward research that would eventually bring dividends in terms of hard cash. Some 80 % of research in the United States is funded by what is called the “military-industrial complex” and is geared toward producing both military and industrial applications.

Subjectivity thus enters science in terms of what is selected for research which itself depends on where the funding is coming from. But values also play an important part in what is actually seen as a problem, what questions are asked and how they are answered. For example, cancer rather than diabetes may be seen as a problem even though they may both claim the same number of victims. Here both political and ideological concerns, as well as public pressure, can make one problem invisible while focusing attention on

another. Moreover, if, for example, the problem of cancer is defined as finding a cure then the benefits of the scientific research accrue to certain groups, particularly the pharmaceutical companies. But if the function of scientific research is seen as eliminating the problems of cancer from society, then another group benefits from the efforts of research: the emphasis here shifts to investigating diet, smoking, polluting industries, and the like. Similarly, if the problems of the developing countries are seen in terms of population, then research is focused on reproductive systems of Third World women, methods of sterilization, and new methods of contraceptives. However, if poverty is identified as the main cause of the population explosion then research would take a totally different direction: the emphasis would have to shift to investigating ways and means of eliminating poverty, developing low cost housing, basic and cheap health delivery systems, and producing employment generating (rather than profit producing) technologies. The benefits of scientific research would go to the Third World poor rather than Western institutions working on developing new methods of contraceptives and companies selling these contraceptives to developing countries. Thus both the selection of problems and also their framing in a particular way are based on value criteria.

It can be legitimately argued that these factors are external to science, that within science, the scientific method ensures neutrality and objectivity by following a strict logic – observation, experimentation, deduction, and value-free conclusion. But scientists do not make observations in isolation. All observations take place within a well defined theory. The observations, and the data collection that goes with them, are designed either to refute a theory or provide support for it, and theories themselves are not plucked out of the air. Theories exist within paradigms – that is a set of beliefs and dogmas. The paradigms provide a grand framework within which theories are developed and make sense, and observations themselves have validity only within specific theories. Thus, all observations are theory laden, and theories themselves are based on paradigms

which in turn are burdened with cultural baggage. All of which raises the question: can there ever be such things as value-neutral “objective facts”? Studies of scientists working in laboratories have shown that the scientific method, by and large, is a myth. Researchers seldom follow it in the linear fashion that exists in the text books. Neither do they ascertain new “facts” suddenly out of the blue. And the same holds true of the laws of nature they are supposed to be discovering. It appears that scientists do not actually “discover” laws of nature; they manufacture them. Scientific knowledge advances by a process of manufacturing which involves thousands and thousands of workers assembling “facts” which through peer review and other procedures end as description or laws of nature.

Value judgments are also at the very heart of a common element of scientific technique: statistical inference. When it comes to measuring risks, scientists can never give a firm answer. Statistical inferences cannot be stated in terms of “true” or “false” statements. When statisticians test a scientific hypothesis they have to go for a level of “confidence”. Different problems are conventionally investigated to different confidence-limits. Whether the limit is 95 % or 99.9 % depends on the values defining the investigations, the costs, and weight placed on social, environmental, or cultural consequences. In most cases, the importance given to social and environmental factors determines the limits of confidence and the risks involved in a hazardous scientific endeavor. For example, when a chemical plant is placed in an area with an aware and politically active citizenry the risks are worked out to a high level of confidence. However, when one is located in an area where the citizens themselves are ignorant of the dangers and do not command political power, the confidence levels are much more relaxed. The people of Bhopal and Chernobyl know this to their cost.

But it is not just in its institutions and method that science is value laden. The very assumptions of science about nature, universe, time, and logic are ethnocentric. In modern science, nature is seen as hostile, something to be dominated. The Western “disenchantment of nature” was a

crucial element in the shift from the medieval to the modern mentality, from feudalism to capitalism, from Ptolemaic to Galilean astronomy, and from Aristotelian to Newtonian physics. In this picture, “Men” stand apart from nature, on a higher level, ready to subjugate and “torture” her, as Francis Bacon declared, in order to wrestle out her secrets. This view of nature contrasts sharply with how nature is seen in other cultures and civilizations. In Chinese culture, for example, nature is seen as an autonomous self-organizing entity which includes humanity as an integral part. In Islam, nature is a trust, something to be respected and cultivated and people and environment are a continuum – an integrated whole. The conception of laws of nature in modern science drew on both Judeo-Christian religious beliefs and the increasing familiarity in early modern Europe with centralized royal authority, with royal absolutism. The idea that the universe is a great empire, ruled by a divine logos, is, for example, quite incomprehensible both to the Chinese and the Hindus. In these traditions the universe is a cosmos to which humans relate directly and which echoes their concerns. Similarly, while modern science sees time as linear, other cultures view it as cyclic as in Hinduism or as a tapestry weaving the present with eternal time in the Hereafter as in Islam. While modern science operates on the basis of either/or Aristotelian logic (X is either A or non- A), in Hinduism logic can be fourfold or even sevenfold. The fourfold Hindu logic (X is neither A , nor non- A , nor both A and non- A , nor neither A nor non- A) is both symbolic as well as a logic of cognition and can achieve a precise and unambiguous formulation of universal statements without quantification. Thus the metaphysical assumptions of modern science make it specifically Western in its main characteristics.

The metaphysical assumptions of modern science are also reflected in its contents. For example, certain laws of science, as Indian physicists have begun to demonstrate, are formulated in an ethnocentric and racist way. The Second Law of Thermodynamics, so central to classical physics, is a case in point: due to its industrial origins the

Second Law presents a definition of efficiency that favors high temperatures and the allocation of resources to big industry. Work done at ordinary temperature is by definition inefficient. Both nature and the non-Western world become losers in this new definition. For example, the monsoon, transporting millions of tons of water across a subcontinent is “inefficient” since it does its work at ordinary temperatures. Similarly, traditional crafts and technologies are designated as inefficient and marginalized. In biology, social Darwinism is a direct product of the laws of evolutionary theories. Genetic research appears to be obsessed with how variations in genes account for differences among people. Although we share between 99.7 (unrelated people) and 100 % (monozygotic twins) of our genes, genetic research has been targeted toward the minute percentage of genes that are different in order to discover correlations between genes and skin color, sex, or “troublesome” behavior. Enlightened societal pressures often push the racist elements of science to the sidelines. But the inherent metaphysics of science ensures that they reappear in new disguise. Witness how eugenics keeps reappearing with persistent regularity. The rise of IQ tests, behavioral conditioning, fetal research, and sociobiology are all indications of the racial bias inherent in modern science.

Given the Eurocentric assumptions of modern science, it is not surprising that the way in which its benefits are distributed and its consequences are accounted for are themselves ethnocentric. The benefits are distributed disproportionately to already over-advantaged groups in the West and their allies elsewhere, and the costs disproportional to everyone else. When scientific research improves the military, agriculture, manufacturing, health, or even the environment, the benefits and expanded opportunities science makes possible are distributed predominantly to already privileged people of European descent, while the costs are dumped on the poor, racial and ethnic minorities, women, and people located at the periphery of global economic and political networks. Science in developing countries has persistently reflected the priorities of the West, emphasizing the needs

and requirements of middle class western society, rather than the wants and conditions of their own society. In over six decades of science development, most of the Third World countries have nothing to show for it. The benefits of science just refuse to trickle down to the poor.

But modern science is not only culturally biased toward the West: it represents the values of a particular class and gender in Western societies. As feminist scholars have shown, science in the West has systematically marginalized women. Women, on the whole, are not interested in research geared toward military ends, or torturing animals in the name of progress, or working on machines that put one's sisters out of work. But more than that, even the least likely fields and aspects of science bear the fingerprints of androcentric projects. Physics and logic, the prioritizing of mathematics and abstract thought, the so-called standards of objectivity, good method and rationality – feminist critique has revealed androcentric fingerprints in all. This is the case, for example, in the mechanistic model of early modern astronomy and physics, in modern particle physics, and in the coding of reason as part of ideal masculinity. The focus on quantitative measurements, variable analysis, impersonal and excessively abstract conceptual schemes is both a distinctively masculine tendency and one that serves to hide its own gendered character. Science has tried to hide its own masculine nature in other ways, by, for example, making women themselves objects in scientific investigation. It was not entirely accidental that sexology became a major science at the same time as women in the West were fighting for the vote and equal rights in education and employment. A number of studies have shown that scientific work done by women is invisible to men even when it is objectively indistinguishable from men's work. Thus, it appears that neither social status within science nor the results of research are actually meant to be neutral or socially impartial. Instead, the discourse of value-neutrality, objectivity, and social impartiality appears to serve projects of domination and control.

The history of science bears this out. The evolution of Western science can be traced back

to the period when Europe began its imperial adventure. Science and empire developed and grew together, each enhancing and sustaining the other. In India, for example, European science served as a handmaiden to colonialism. The British needed better navigation so they built observatories and kept systematic records of their voyages. The first sciences to be established in India were, not surprisingly, geography, and botany. Western science progressed primarily because of the military, economic, and political power of Europe, focusing on describing and explaining those aspects of nature that promoted European power, particularly the power of the upper classes. The disinterested commitment of European scientists to the pursuit of truths had little to do with the development of science. The subordination of the blacks in the ideology of the black "child/savage" and the confinement of the white women in the cult of "true womanhood" emerged in this period and are both by-products of the Empire. While the blacks were assigned animal and brutish qualities the white women were elevated and praised for their morality. While the blacks were segregated and enslaved, the women were placed in narrow circles of domestic life and in conditions of dependency. Racist and androcentric evolutionary theories were developed to explain human behavior and canonized in the history of human evolution. The origins of Western, middle class social life, where men go out to do what men have to do, and women tend the babies and look after the kitchen, are to be found in the bonding of "man-the-hunter"; in the early phases of evolution women were the gatherers and men went out to bring in the beef. Now this theory is based on little more than the discovery of chipped stones that are said to provide evidence for the male invention of tools for use in the hunting and preparation of animals. However, if one looks at the same stones with different cultural perceptions, say one where women are seen as the main providers of the group – and we know that such cultures exist even today – you can argue that these stones were used by women to kill animals, cut corpses, dig up roots, break down seed pods, or hammer and soften tough roots to prepare them for

consumption. A totally different hypothesis emerges and the course of the whole evolutionary theory changes.

Thus the cultural, racial, and gender bias of modern science can be easily distinguished when it is seen from the perspective of non-Western cultures, marginalized minorities, and women. The kinds of questions science asks when seeking to explain nature's regularities and underlying causal tendencies, the kinds of data it generates and appeals to as evidence for different types of questions, the hypotheses that it offers as answers to these questions, the distance between evidence and the hypothesis in each category, and how these distances are traversed – all have the values of white middle class men embedded in them. Put simply, this implies a relativism in science as in any other sphere of human knowledge. However, most scientists do not look kindly toward criticism, or sociological, philosophical, historical, and anthropological studies which highlight science's value laden nature. Relativism is anathema to scientists: many believe that they are engaged in revealing nature's absolute truths. Science, they argue, is special and different from any other body of knowledge: it is counter-intuitive and rarely a matter of common sense. Some propagandists for science have even suggested that the entire discipline of the sociology of knowledge is a conspiracy of the academic left against science.

The idolization and mystification of science, the insistence on its value neutrality and objectivity, is an attempt not only to direct our attention away from its subjective nature but also from the social and hierarchical structure of science. Whenever we think of "the scientists" we imagine white men in white coats: the sort of chaps we see in advertisements for washing power and skin care preparations, standing in a busy laboratory behind a Bunsen burner and distillation equipment telling us how the application of science has led to a new and improved soap or cold cream. This view of scientists is not far from reality. True power in science belongs to white, middle-aged men of upper classes. Everyone else working in science – women, minorities, black men, white men of lower classes, and third world

researchers – are actually basically rank and file laboratory workers. The social hierarchy within science by and large preserves absolute social status, the social status scientific workers hold in the larger society. The people who make decisions in science, who decide what research is to be done, what questions are going to be asked, and how the research is going to be done are a highly selective, tiny minority. These people have the right background, the contacts to get the necessary appointments, and then further contacts to secure funding for their research projects. The actual execution of scientific research, the grinding and repetitive laboratory work, is rarely done by the same person who conceptualizes that research; even the knowledge of how to conduct research is rarely possessed by those who actually do it. This is why the dominant (Western) social policy agendas and the conception of what is significant among scientific problems are so similar. This is why the values and agendas important to white, middle class men pass through the scientific process to emerge intact in the results of research as implicit and explicit policy recommendations. This is why modern science has become an instrument of control and manipulation of non-Western cultures, marginalized minorities, and women.

Even if we were to ignore all other arguments and evidence, the very claim of modern science to be value-free and neutral would itself mark it as an ethnocentric and a distinctively Western enterprise. Both claiming and maximizing cultural neutrality is itself a specific western cultural value: non-Western cultures do not value neutrality for its own sake but emphasize and encourage the connection between knowledge and values. By deliberately trying to hide its values under the carpet, by pretending to be neutral, by attempting to monopolize the notion of absolute truth, Western science has transformed itself into a dominant and dominating ideology.

Varāhamihira

K. V. Sarma

Madras, Tamilnadu, India

Varāhamihira, who flourished in Ujjain, in Central India, during the sixth century, was perhaps the greatest exponent of the twin disciplines of astronomy and astrology in India. A master of all three branches of the disciplines astronomy, natural astrology, and horoscopic astrology, he was a prolific writer whose works number more than a dozen, some of which are extensive.

Varāhamihira was born in Kāpithaka, present-day Kapitha, in Uttar Pradesh, known also as Saṅkāśya and mentioned as a great center of learning by the Chinese pilgrim Yuan Chwang as Kah-pi-t'a. He was the son of Ādityadāsa and a Śakadvīpī brāhmaṇa of the Maga sect, who were sun worshippers. His renown has caused several legends, both Hindu and Jain, being woven round his birth, growth, and predictive propensity. A legend has it that he was one of the nine luminaries of the court of King Chandragupta II Vikramāditya, but the definitively known date of Varāhamihira goes against this identification. Varāhamihira's patron has now been identified as King Mahārājādhirāja Dravyavardhana, who ruled over Ujjain during the middle of the sixth century. Varāhamihira also possessed great poetic talents, so that some of the later rhetoricians have extracted verses from his writings to illustrate poetic qualities. Indeed, the fame of Varāhamihira has even induced several places in India to be named after him.

K. V. Sarma: deceased

It is a characteristic of Varāhamihira that he produced larger and shorter versions of most of his works. His only work on astronomy is *Pañcasiddhāntikā* (The Five Basic Texts), being a redaction of select topics from the basic texts of five earlier astronomical schools: *Vāsiṣṭha*, *Paitāmaha*, *Romaka*, *Pauliśa*, and *Saura*, in 443 verses, in the form of a work manual.

Varāhamihira wrote several astrological works. In his *Bṛhajjātaka* (Large Horoscopy), also called *Horāśāstra* (Science of Hours), in 25 chapters containing about 400 verses, he treated all conceivable topics on the subject. This work has been a model for later works and is highly popular even today. In this work, Varāhamihira exhibits his understanding of Greek astrology and employs the Sanskritized forms of a number of Greek terms. His *Laghujātaka* (Shorter Horoscopy) is an abridged form of the previous work. On marriage and the prediction of auspicious times to marry, Varāhamihira composed two works: the *Bṛhadvivāha-ṣaṭṭala* (Larger Treatise on Marriage) and its abridgement, the *Svalpa-vivāha-ṣaṭṭala*. Prognostication on military marches and domestic journeys was treated in three works: *Bṛhad-Yoga-Yātrā* (Larger Course on Expedition), in 34 chapters, *Yoga-yātrā* (Course on Expedition), and *Svalpa-yātrā* (Shorter Course on Expedition).

On natural astrology, Varāhamihira's major work is the *Bṛhatsaṃhitā* (Large Compendium), the *Svalpa-saṃhitā* (Shorter Compendium), and *Vaṭakaṇikā* (Short Text), the last two known only through profuse quotations in later works. The *Bṛhatsaṃhitā*, in 106 chapters, is an encyclopedic compendium on numerous subjects relating to life and nature, such as physical astronomy, geography, calendar, meteorology, flora, portents, agriculture, economics, politics, physiognomy, engineering, botany, industry, zoology, erotica, gemology, hygiene, omens, and prognostication on the basis of asterisms, lunar days, etc. A fund of material on applied science, physical observation, and deduction on the basis of statistics and experimentation went into the production of this work, which is perhaps unparalleled in the early literature of the world. Varāhamihira's works, set

in precise terminology and in graceful language, have been models for writers of later times, not only in astronomy and astrology but in other disciplines as well.

Vaṭeśvara

Manu V. Devadevan

Archive India Institute, Bhubaneswar, Odisha, India

Vaṭeśvara, son of Mahādatta Bhaṭṭa, was a tenth-century Indian astronomer from a town in the Kashmir valley. Some accounts name Ānandapura as the place of his birth. He is the

author of the *Vaṭeśvara Siddhānta*, which he completed at the age of 24, in 904 CE (Śaka 826). Al-Bīrūnī refers to a work called *Karaṇasāra*, which he says was written by Viṭṭeśvara, son of Mihadatta. It is likely that this astronomer is the same as Vaṭeśvara. According to al-Bīrūnī, Viṭṭeśvara was born in Nāgarapura.

Although the *Vaṭeśvara Siddhānta* survives only in a solitary manuscript found at Lahore, it seems to have been a widely read work for a long time. Its influence is seen on major astronomers like Śrīpati, Bhāskara II, and Kamalākara Bhaṭṭa. Vaṭeśvara was an Āryabhaṭan by persuasion and adopted several stances taken by the great pioneer. For instance, most astronomers divide the *Mahāyuga* of 43,20,000 years into the four *yugas*, the *Kṛta*, *Tretā*, *Dvāpara*, and *Kali* in a 4:3:2:1 ratio. But Vaṭeśvara followed Āryabhaṭa and assigned a period of 10,80,000 each for the four *yugas*. In doing so, he made a strong attempt to refute Brahmagupta's criticism of Āryabhaṭa.

In 1,326 verses divided into eight chapters, the *Vaṭeśvara Siddhānta* covers a wide range of issues related to astronomy, including mean motion, true motion, calculation of aeonary days, corrections to mean planet, diurnal motion, eclipses, heliacal rising, lunar horns, and the conjunction of celestial bodies. The chapters are further divided into shorter sections devoted to different aspects of astronomy, which is not to be seen in any other astronomical treatise from India.

Vaṭeśvara set very high standards for the professional astronomer. For instance, he held that an ace astronomer must be able to determine the *ahargaṇa* (number of days elapsed in an era) on the basis of solar days alone, without taking recourse to lunar months, intercalary months, etc. The astronomer was also expected to find lunar days from civil days, solar days from lunar days, and sidereal days from solar days. Not only was the astronomer required to know how to arrive at the longitude of the sun and the moon but also determine the sun's longitude from the moon's and the moon's from the sun's! Vaṭeśvara offered a number of innovative methods and fresh interpretations, which along with its

encyclopedic character made his treatise an important source of reference for astronomers in India for a long time.

Veterinary Medicine in India

Guy Mazars

A tradition of veterinary therapy developed very early in India. Modelled on Āyurveda, (Āyurveda is a holistic medical system that is explained in detail in an article in the encyclopaedia) this veterinary medicine is known through a specialised literature which tells us about the ancient methods of prevention and treatment of animal diseases in India before the advent of modern medicine (Mazars, 1994, 1999). Some of these treatments, as yet little known outside India, are still practised today.

The surviving texts are concerned mainly with the treatment of horses and elephants. The legends incorporated in these texts present knowledge regarding the medical treatment of horses and elephants as being directly revealed by the gods. This may be explained partly by the need to provide veterinary medicine with an origin similar to that of the Āyurveda, which is also presented as 'divinely inspired' knowledge. In fact, veterinary medicine developed from the ayurvedic model over the seven or eight centuries which preceded the Christian era. It is also known, from the inscriptions of Aśoka in the middle of the third century BCE, that this

Buddhist sovereign opened hospitals for animals (Schneider, 1978). Unfortunately, no actual veterinary records exist from this period.

The oldest Sanskrit text of veterinary medicine that has come down to us is a treatise entitled *Aśvāyurvedasiddhānta* (Complete System of Āyurveda for Horses) attributed to a certain Śālihotra (Mukhopadhyaya, 1926, pp. 356–399). This text is probably dated before the tenth century. There also exists a Tibetan version written at the beginning of the eleventh century, and the text was translated into Persian in the fourteenth century. Subsequently, various treatises on horses and diseases of horses were composed. The principal surviving ancient text dealing with elephant medicine is a treatise which tradition ascribes to Pālakāpya, a legendary person, also known as Dhanvantari, the father of Indian surgery (Mukhopadhyaya, 1926, pp. 400–424). The text, entitled *Hastyāyurveda* (The Āyurveda of Elephants), is divided into four parts. The first part is devoted to general diseases, the second to localised and minor ailments, the third to surgery and anatomy, and the last to the feeding of elephants and medicinal preparations. The text cannot be earlier than the Middle Ages, but it contains medical concepts and veterinary practices of long standing.

Specialised treatises are not the only source of existing information. The treatises of the Āyurveda sometimes refer to veterinary treatments. Thus, a passage in *Carakasamhitā* (Siddhisthāna, XI, 20–26) contains a list of ingredients for preparing enemas for elephants, camels, cattle, horses, and sheep (Sharma, 1983, pp. 665–666). There is also information on animal-borne human diseases. For example, rabies is described under the name *jalatrāsa* (hydrophobia) in the *Suśrutasamhitā* (from the beginning of the Christian era) (Bhishagratna, 1963, pp. 733–734). A small collection of therapeutic formulae from the eleventh century, the *Rājamārtanḍa*, contains a chapter devoted to the treatment of domestic animals (Misra, 1966, pp. 108–112). In addition, certain nonmedical texts contain information on the veterinary art. Some information regarding veterinarians is contained in the *Arthaśāstra* (Kangle,

1960–1963), a treatise of government traditionally attributed to Kauṭilya, possibly an adviser to Chandra Gupta (313–289 BCE), founder of the Maurya dynasty.

In the field of anatomy the knowledge of the ancient Indian veterinarians seems to have been quite extensive and is more accurate than that concerning the human body. Observations on animal carcasses were favoured by sacrifices, wars and other events. As regards the physiopathological conceptions in the Sanskrit texts of veterinary medicine, they are those of classical Āyurveda. According to these conceptions the health of both animals and human beings depended on the normal balance and proper functioning of the three vital principles: wind (*vāyu*), bile (*pitta*) and phlegm (*kapha* or *śleṣman*). Generalised diseases and localised ailments were linked to imbalance in these principles, or disturbances in the secondary forms of a single principle. Consequently, the name *tri-doṣa* (three troubles) was given to this triad of elements. Disorders in the functions governed by the three principles were themselves the outcome of multiple causes related to behaviour, character, feeding, mode of life, season, habitat, etc. In particular, equestrian texts often invoked a nutritional cause: food poisoning or unbalanced feeding.

Classification of diseases was broadly similar to the principles applied to human diseases but differed in detail, except in certain cases such as the diseases common to horses and human beings. The various conditions were classified according to their supposed origin, their apparent seat, or the nature of the symptoms. In the first category were diseases attributed to a disorder of wind, bile, etc. Diseases of wind were the most numerous, totalling 76 in the case of elephants. In the second category were diseases of the skin and the head, chest pains, etc. The last category notably included fevers, which were differentiated into many types according to the involvement of wind, bile or phlegm, and according to the other symptoms which accompany hyperthermia. One of the most detailed classifications is that of the *Hastyāyurveda*, which placed diseases of elephants in two broad groups. The first group was

endogenous diseases, including diseases attributable to disturbance of the vital principles. The second group was exogenous diseases, mainly traumatic injuries: accidental wounds and those caused by weapons, bites of wild animals, etc. However, identification of the diseases listed in the texts is often uncertain, and sometimes even impossible, due to a lack of information. The passage in the *Suśrutasamhitā* (Kalpasthāna, VII, 43–50) concerning rabies was translated as follows: ‘The bodily Vāyu in conjunction with the (aggravated) Kapha of a jackal, dog, wolf, bear, tiger, or any other such ferocious beast affects the sensory nerves of these animals and overwhelms their instinct and consciousness. The tails, jaw-bones and shoulders of such infuriated animals naturally droop down, attended with a copious flow of saliva from their mouths. The beasts in such a state of frenzy, blinded and deafened by rage, roam about and bite each other’. The text states further: ‘A person bitten by a rabid animal barks and howls like the animal by which he is bitten, imitates it in many other ways and, bereft of the specific functions and faculties of a human subject, ultimately dies...’ (Bhishagratna, 1963, pp. 733–734).

As in Ayurvedic medicine, prevention occupies an important place. It is based on general and dietary hygiene. The texts lay stress on the layout and maintenance of cowsheds and stables, the different sorts of foods with their qualities and their drawbacks, as well as on the dietary rules to be observed. They underline the importance of moderation in food for domestic animals and enumerate the undesirable consequences of an excess of food. Furthermore, like Āyurveda, the veterinary tradition of India emphasises methods aimed at strengthening the general state of health, notably by the use of tonics and stimulants (*rasāyana*), and aphrodisiacs (*vājīkaraṇa*). The latter, containing various constituents, which have been the object of little study to date, augmented the strength of enfeebled animals and those of poor virility. Sanskrit texts provide various recipes for potions enabling a stallion to mate repeatedly. The *rasāyana* (elixirs of long life) were prescribed to strengthen animals and were recommended for preventing

all sorts of illnesses. For example, a mixture based on aconite and three sorts of peppers was recommended for extending the life span of horses. The following plants were main constituents of such elixirs: *Asparagus racemosus* Willd., *Emblica officinalis* Gaertn., *Terminalia bellerica* Roxb., *Terminalia chebula* Retz., *Tinospora cordifolia* (Willd.) Miers and *Zingiber officinale* Rosc. Buffalo horn was also a valued ingredient.

Veterinary medicine is theoretically divisible into eight branches, corresponding to the eight divisions set out in the Āyurveda. Thus, hippiatry was divided into general surgery, general therapeutics, ophthalmology and otorhinolaryngology, care of foals (corresponding to Ayurvedic paediatrics), toxicology, fortifying treatments, demonology, and the use of aphrodisiacs. Apart from surgical operations, therapy consists most often in the administration of medicinal preparations by different routes and under different forms: mixtures of powders, decoctions, electuaries, ointments... The texts lay stress quite particularly on the benefits of using medicinal oils and butters in food, in external applications and in enemas. We find also various procedures intended to make horses sweat, techniques of cauterisation, bloodletting and several kind of enemas. Procedures of inducing sweating, eight in number, are indicated for treating the sicknesses due to wind and to phlegm. The texts of hippiatry distinguish between violent and mild sudorifics. They specify the method of use of each by indicating the most favourable periods for this type of treatment. Cauterisations with red-hot irons are reserved for the treatment of diseases which neither dietary regimes, nor errhines, nor enemas have been able to cure. The sites to be cauterised and the form and the number of the cauterisations vary according to the case to be treated. We are well informed also on the post-operative care and the precautions to be taken in the days that follow the operations. We note also the use of caustics. As far as bloodletting is concerned, the treatises on hippiatry tell us also about the contra-indications and indicate the food for ‘reconstituting’ the blood and the remedies to be administered if the bloodletting is substantial.

Since India gained its independence in 1947, the Indian Government, recognising the services rendered by traditional medicine, has given a new impetus to these practices. The study and practice of traditional medicine has been regulated, and training is provided at present by a large number of schools with associated hospitals and care centres. This movement has also benefited traditional veterinary medicine, which has undergone a revival.

Several Indian laboratories now produce preparations from ancestral recipes, which are packed under modern conditions and sold throughout India for the treatment of domestic animals. Traditional formulations produced on a large scale include tonics, fortifiers and digestives, as well as antiparasitic and antifungal products. Many of these medicaments are polyvalent, due to the multiplicity of ingredients used in their preparation. For example, a company in Bangalore produces a stomachic and tonic containing 59 ingredients. This preparation is recommended for treating digestive disorders (anorexia, dyspepsia, constipation, etc.) in cattle, sheep, goats, horses and dogs, in doses proportional to the size of these animals. The principal ingredients of vegetable origin include the following: *Aegle marmelos* Corr., *Aquilaria agallocha* Roxb., *Butea monosperma* (Lam.) Kuntze, *Centratherum anthelminticum* Kuntze, *Curcuma longa* L., *Ferula narthex* Boiss., *Moringa oleifera* Lam., *Piper longum* L., *Punica granatum* L., *Terminalia bellerica* Roxb., *Terminalia chebula* Retz., *Tinospora cordifolia* (Willd.) Miers, *Trachyspermum ammi* (L.) Sprague and *Zingiber officinale* Rosc. These ingredients were prescribed in Ayurvedic medicine for their aperitive, digestive, stomachic, carminative or anthelmintic properties. Another example is provided by an ointment against sprains and sores, prepared from the following plants: *Abrus precatorius* L., *Acorus calamus* L., *Celastrus paniculatus* Willd., *Hyoscyamus niger* L., *Moringa oleifera* Lam., *Nardostachys jatamansi* D.C., *Ocimum sanctum* L., *Saussurea lappa* C.B. Clarke and *Vitex negundo* L. To these oils are added extracts of seven other plants: *Anacyclus pyrethrum* D.C., *Colchicum luteum* Baker, *Curcuma amada*

Roxb., *Gloriosa superba* L., *Litsea sebifera* Pers., *Myrica nagi* Thunb. and *Nerium odoratum* Sol. All these plants have been investigated and their active principles are known. *Nardostachys jatamansi* is often combined with oil of henbane (*Hyoscyamus niger*) as an antineuritic. *Ocimum sanctum* and *Vitex negundo* are used as wound dressing. In traditional medicine, the root of *Curcuma amada* is applied to contusions and sprains. Extract of *Colchicum luteum* is applied externally as an analgesic (Mazars, 1994, p. 449).

Many plants of the Ayurvedic pharmacopoeia have been shown to be effective. Listing and identification of the many plant species used in preparing remedies described in the ancient medical literature was accomplished during the 1970s. Veterinary applications of these medicines were also taken into account. Despite the increase in chemical and pharmacological studies in recent years, there is still much to be done in evaluating the resources of India with regard to medicinal plants, which may be useful in veterinary medicine.

Long before the development of veterinary medicine in the West, the veterinary tradition of India had already originated a large body of theoretical and practical knowledge. Before the advent of modern medicine and the discovery of antibiotics, the knowledge of veterinarians in the West was not much further advanced than that of their Indian predecessors. Certain aspects of ancient veterinary medicine in India, neglected or unknown in the West, merit deeper study. These include the ideas regarding the feeding of animals, preventive methods and cauterisation techniques. Also of interest are the medicines derived from plants which are still in use, as well as those medicines which are no longer used but are fully described (together with indications, and mode of preparation and administration) in ancient texts.

Veterinary Medicine in Iran

H. Tadjbakhsh

Department of Veterinary Sciences, The
Academy of Sciences of Iran, Tehran, Iran

Veterinary medicine was known in Iran from the time of the Sassanids (212–652 AD). They treated useful animals with drugs or surgical operations. Veterinarians received wages and each animal had a tariff of its own. General practice was the same in human and veterinary medicine, but the duties of physicians and veterinarians have been separate since the Sassanid reign. Administration of a vast country like Iran with so many poor roads required the transport of army equipment to meet public demands. Domesticated draught animals, such as horses, mules, and camels, received special attention. This called for a disciplined veterinary organization. Veterinarians, especially army veterinarians, were celebrated figures in the country. In ancient Iran there were more veterinary clinics than in other countries of the world at that time (Elgood, 1974).

There were almost 70 important offices in the Sassanid government. One of the important offices related to horses and other domesticated animals and was administered by the head equerry (*Akhvarbadh* = *Hwrpt*). This head equerry was one of the key figures responsible for animal husbandry and veterinary organization. Another senior official was *Nhcyrpt* (master of the hunt) who was responsible for hunting affairs, breeding and treating hunter animals and birds or wildlife in modern-day terminology. The head equerry and master of the hunt had other responsibilities that sometimes were nonveterinary, but they were aware of veterinary

affairs and sometimes they were veterinarians. There were also second-class equerries who offered veterinary services especially to the horses. Ruminants were not paid equal attention. Experienced shepherds or rustic veterinary technicians treated them.

In the Sassanid reign, Becheshk Sotur (Quadruped Doctor) was the one in charge of treating army horses. He was an important figure. According to *Mafatih al-Olum* (Keys to Sciences) of Kharazmi, there were almost seven forms of writing for registering accounts and provisions. *Dad Dafira* was used for writing justice rules and *Ahur Hamar Dafira* was used for keeping the accounts of stables and horses. These forms of writings belonged to seven secretariats or ministries, and one of them was the Ministry of Stables that dealt with livestock affairs.

During the Sassanid era, veterinary medicine was separated from human medicine as a specialized art and profession, although it shared its roots with medicine. These two fields were unified to some extent in post-Islam Iran and some of the celebrated physicians of the time wrote independent treatises on veterinary medicine or allocated chapters of their medical collections to this field. Meanwhile, some of these people researched animal diseases and treated horses and birds of prey. However, there were certain people who practiced solely in the veterinary field during all the centuries since Islam. They had their own special clinics or offices and did not practice human medicine.

In Iran of the Islamic period and in other Muslim countries, they recognized the similarities between medicine and veterinary medicine, but at the same time they believed in their independence from each other. The most important duty of veterinarians was in treating and preventing equine diseases, because this animal was important to them in war and in performing the Hajj.

The Iranian state-run veterinary system was divided between the head equerry organization and the Investigation Department. The head equerry's organization was a well-organized department that took care of the health of animals in state studs and stables. In addition to these, the

investigating departments inspected the affairs of the stables, and cookery inspectors were busy with food hygiene inspection. Documents suggest that veterinarians headed all these practices.

Private veterinarians had their own special veterinary associations and veterinary regulations. They treated horses, mules, asses, and camels in their clinics or in their cottages. When there were disputes between the animal owner and veterinarian, the master of veterinarians or chief of the veterinary association intervened and reported the result to the market inspector for a final ruling. The final arbiter was the market inspector who also administered tests and issued certificates for veterinarians.

In the ancient Iranian and eastern world, people attached special significance to breeding and treating horses and birds of prey but not to ruminants. Perhaps one reason was the abundance of these animals, as there were vast ranges and low population densities. There was little need for treating ruminants, because these animals were religiously permitted meat, and so people slew them at times of probable danger and ate them if they were not rotten. But there was a dire need for horses, for protecting state borders, consolidating the ruler's power, and carrying food and ammunitions. People did not eat the flesh of these animals; they had to cure them.

The places and routes for keeping or trafficking horses, mules, asses, and camels, was chiefly in the cities, suburbs or probably in the studs, but the ruminants were kept in villages and suburban areas. Veterinarians and educated physicians depended on urban life and tended to work in developed areas. This is why, until the early twentieth century, rustic eastern communities had little access to physicians and veterinarians. People had to learn medicine, veterinary medicine, and midwifery through their own experiences.

Iranian Veterinarians and Hippologists

Fakhr Modabber, in his *Adab al-Harb*, alludes to a hippologist and horse master named Muhammad Marzbān, who visited Hadjaj, the ruler of

Iraq, in the company of Ibn Qerryah (d. 703) a great man-of-letters and horse master in Iraq. He said, "Marzban is the mother and father of this profession." That means that he is a master in hippology (the study of the horse). Ibn Qerryah was himself a student of Marzban. Marzban thought there was a direct link between the color and efficiency and physiological properties of horses. "A dark bay horse is good for war, a gray or white horse is good for plains, a piebald horse is good for hunting, a dun horse is good for visiting friends and walking, a colored horse is suitable for playing polo and a grass-green blond horse is the best for escaping." He then gave anatomical characters of the horse in great detail and in beautiful words. Marzban is a famous Iranian name meaning chief. According to the *Adab al-Harb* the title of horse master was attributed to a veterinarian skilled in raising horses.

The most renowned and best learned of the veterinarians of the first three centuries was Ibn Akhi Hozam, the chief of veterinary medicine and stockbreeding affairs of Motavakkel of Abbasids (d. 861). He was Iranian by birth and his father and uncles were all skilled veterinarians. His magnum opus lists the names of some notable veterinarians such as Abu Qoreh and Muhammad ibn Suleyman ibn Ghaleb, who was apparently a relative of Hozam.

Pre-Mongolian Veterinary Organization of Iran

In the administrative chart of Iran, the grand vizier or prime minister was second in administrative rank to the Sultan. The viziership was for some time hereditary in some families such as Jeyhani, Balami, and Nezam al-Mulk. There were almost ten tribunal courts in the office of the grand vizier, such as the Inspector's Court (*Divan Moshref*), *Mohtasseb*, *Saheb-e Barid* (which was responsible for mounted couriers), and the equerry office. This last was responsible for breeding horses, news dispatches, taking care of the pony express, veterinary medicine and inspecting livestock and food.

Breeding horses and training them for war were the chief responsibilities of the head equerry. The Moshref was in charge of animal health, administering veterinarians' affairs and other affairs related to animals. The inspectors' organizations and a number of other Seljukids administrative systems were in force until the end of the nineteenth century but changes occurred in the course of time in the nature and sometimes in the names and terms.

Any business, including medicine and veterinary medicine, had a chief of its own. These people, in addition to observing professional rules and regulations, were in charge of collecting taxes from the businessmen and industrialists. In some cases they defended the rights of their guild members against the government.

During the Ghaznavid dynasty, the head equerry was a distinguished title in the administrative system and army. It was the same during the Seljukid's reign. Ibn Abi Toba Nassir al-Din Kharazmi (killed 1,135), the Shafite vizier of Sultan Sanjar, was born in Merv and entered the court of the sultan upon learning the sciences of the time. He was skilled in inspecting the stables and food hygiene service and in veterinary medicine and stockbreeding. He served for a short time in the beginning. Twice he was appointed minister of Sultan Sanjar but was jailed following a conspiracy of one of the emirs of the Sultan and died in prison. He was a patron of scientists and authors. Ekhtiar al-Din Kushli was one of the head equeries at the court of Kharazmshah who fought in the Mongolian raid on Bukhara and was killed.

Veterinarians and Their Activities (Tenth to Thirteenth Centuries)

Veterinarians carried out their duties in the state veterinary service or as private practitioners. Some had veterinary offices. Veterinarian masters and sometimes master physicians, skilled in both medicine and veterinary medicine, wrote books on horses and their diseases. Abū Rayḥān Bīrūnī in his *Al-Tafhīm*, writing about of astrology from a Persian point of view, cited various

professions such as veterinary medicine and its relation with the stars. Fakhr al Din Rāzī in his *Djama al-Olum* in the *Treatise on Al-Baytara* wrote about the activities of the veterinarians.

Physicians Writing About Veterinary Medicine

Many physicians of Iran and the world of Islam have written about veterinary medicine and zoology. Ibn Baytar belonged to a family of veterinarians living in Andalusia. He wrote a book entitled *Kashf al-Vayl fi Marefat al-Amraz al-Khayl* (Detection of Afflictions in Horse Diseases) that showed his thorough knowledge of veterinary.

Veterinary Organization in the Mongolian and Timurid Periods

Veterinary medicine was a common profession during the thirteenth to fifteenth centuries. Many books were written on veterinary medicine and zoology in Persian or in Arabic, either independently or as chapters of general books. Some of these books are extant. They provide solid evidence about the education of veterinarians during this period.

In *Rozat al-Djannat*, falconers' treating birds of prey was explained. It says that Shams al-Din Kart, king of Herat who fell captive to Abaqa Khan, cured his beloved falcon in 1277. According to Shah-Qoli, the head equerry, Tamerlane was so skilled in veterinary medicine that he performed necropsy to find out reasons for the horse's death. Ibn Arabshah (1436) writes that Tamerlane, in his military march to Damascus, sent a number of veterinarians, physicians, industrialists, and scientists to Samarkand. Veterinary medicine was also a profession of high value in other states of the world of Islam. Ibn Monzer wrote the book *Kamel al-Sanaatayn* at the request of Nasser al-Din Qalavoon, King of Egypt (fourteenth century). Al-Malek al-Mujahed, King of Yemen and Arabia, wrote *Al-Aqval al-Kafia* on veterinary medicine.

Veterinary Organization in the Safavid Era (Sixteenth to Eighteenth Centuries)

Like previous periods, veterinary and animal husbandry affairs in the reigns of the Safavids, Afsharids, and Zands were a chief responsibility of the head equerry, hunt master and inspectors' court. A number of veterinarians cured sick animals in clinics or in the field. The head equerry was an army commander and the third most important person in the nation. According to Mirza Sami'a, he had thousands of men working under him, ranging in rank from second-class head equerry, *Baytar* (veterinarian), inspector of technical and financial affairs, horseshoe maker, cattle breeder, horse groom, technicians, and saddle keepers and setters. There were many organizations related to animal husbandry and wildlife organizations such as organizations for grooms (*Mehtarbashi*), head of cattle or horses (*Ramedarbashi*), head of herd of cows and sheep, grooms of mules and camels, grooms of lions, grooms of dogs, snake handlers, etc.

Investigation Department (*Eshraf*) or Veterinary Organization of the Safavids

There was an organization called *Eshraf* that supervised all governmental affairs both before and after the time of the Safavid reign. Part of their responsibility concerned the supervisors of the quadrupeds, camels, kitchens, etc. They also inspected the stables and studs of the horses and other animals producing food and dairy, and checked on taxes levied on animals. According to Chardin and Mirza Sami'a, the inspectors paid attention to the health of the camels and horses. Special officers studied animal corpses to identify causes of death.

There was a ministry called the head equerry organization that administered the affairs and inspected the health of the horses and other animals. Another organization called *Eshraf*, coequal with a modern-day veterinary organization, was responsible for treating and supervising the technical and financial affairs of the animal breeding sector of the monarchy. The chief of this

organization in the time of the Shah Abbas II was Nezam al-Din Ahmad.

The Veterinary Profession in the Time of the Safavids

Medicine and veterinary medicine in the Safavid reign inherited the traditions and knowledge of the Timurid dynasty.

Amin Ahmad Razi in *Haft Eqlim* (Seven Continents), written in 1601, mentions Romia or Constantinople, where there was a bazaar of veterinarians. There were special bazaars or marketplaces of veterinarians in other Muslim nations. Safavid kings, especially Shah Abbas I and II, paid special attention to breeding horses. At the order of Shah Abbas II, many veterinary books were written. Shah Abbas I used to go to the stables and inspect horseshoes; he knew about horse diseases and means of treatment.

Some of the great veterinarians of the period, as mentioned in the available manuscripts, treatises of falconry and hippology, are Hashemi, Saffi, Nezam al-Din Ahmad, Mohebbi Khan Khas, Majd al-Din bin Muhammad Shafi, Abdullah Khan Bahador, Arab Najafi and a few others.

Department of Veterinary Medicine in the Time of Qajars

In the time of Qajarids (until almost 1921), the department of veterinary medicine was part of the head equerry organization. The head of this department was the deputy chief of the head equerry organization.

Veterinary medicine was an independent job, and although many people contributed to it, as they did with humans, the veterinarians only were responsible for treating animals, especially horses. Another veterinarian and hippologist of the time of Nasser al-Din Shah was Haji Muhammad Qoli Beyq Turkman.

Since the middle of the Qajarid reign, Iranian veterinary medicine gradually lost prestige compared with Western veterinary science. Unfortunately Iranian ancient veterinary medicine

completely fell into oblivion, as did medicine. They could still use bleeding medicine, which is similar to Chinese acupuncture in some of its aspects, and use medicinal herbs observing rules of sanitation.

The political and social instability of Iran in the nineteenth century affected veterinary medicine. "Almost all of the veterinarians and the majority of the peddler physicians are Turkman. Veterinary is confined to a few diseases of horse and mule, and after cauterization and drainage they use purgatives. Since there are no sanitary police, sanitation measures, or veterinary establishments, deadly diseases have killed a greater number of animals making the tribal people poor" (Polak, 1865).

Comte de Gobineau, in his trips to Iran in 1855–1856, mentioned peddler veterinarians but did not attach significance to them. The fact that they said Iranian horses and sheep were the best of these animals in the world, shows that Iranian veterinary medicine must have been well developed.

The first faculty of veterinary medicine in Iran was founded in 1933 in Tehran and the German Dr. Damon, the French Le Louet and seven other German and Hungarian professors plus Iranian army veterinarians who had graduated from France, taught in this faculty.

In between the years 1926 and 1931, 15 civil students left Iran for France to study veterinary medicine. They studied at various schools of veterinary medicine and some of them passed specialized courses. On their return they taught at the Tehran Veterinary Faculty and they replaced foreign professors.

Veterinary Practice in Nepal

Krishna Kaphle

Nepal is a landlocked country lying between 80°04' and 88°12' East longitude, and 26° 22' and 30° 22' North latitude. It extends over an area of 147,181 km² with an average east to west length of about 885 km. The north-south width is not uniform and it varies from a maximum of 245 km to a minimum of 145 km. Politically and geographically Nepal is located between two giant nations, China on the North and India on

Veterinary Practice in Nepal, Table 1 Status of livestock population by ecological zone, 1998/1999

Unit: ('000 no)

the South. The country has three patterns of landscape: the mountains, mid hills and the plains. The plains and hills with valleys are the major sites of human settlement and major cities are located here. Nepal has a population of slightly over 23.15 million. Though the political boundary of Nepal was restructured by the British colonial era occupation in the Indian subcontinent, isolation from the world was almost total until the mid twentieth century. This isolation affected Nepal both in positive and negative ways. On the positive side, when ancient cultures and traditions were safeguarded, progress made elsewhere was slow to be. This has happened with veterinary medicine in Nepal. The tradition of ethno-veterinary medicine awaits revival, while the copied concept of western veterinary system has limited use. This short article describes the historical and contemporary situation of organized veterinary services in Nepal.

Agriculture, the only source of livelihood for most of the Nepalese people, is not only an occupation but also a way of life. About 85.80 % of the population live in rural areas and earn their living from farming, whereas only 6 % live in cities and are involved in non-farming occupations. Livestock is an indispensable part of agriculture, which provides employment to over 80 % of the country's population. Livestock is now looked upon with great expectations as playing a great part for the development of the nation, and attempts are made to boost production. The

efforts are seeing results, with farmers turning to commercial livestock farming which in the past was just a satellite component of agriculture, basically intended for manure production and domestic consumption (APP, 1995). However, in recent years dairy and poultry farming are turning into industries making a large contribution to the national gross domestic product (NGDP). Planners have identified three main ecological components of Nepal to implement various development activities (Carson and Sharma, 1992). The three ecological zones of Nepal have different distributions of livestock numbers, as illustrated in Table 1, with higher numbers in the mid hills. Almost every household in the villages has an animal. The percentage of households keeping livestock and birds by region is shown in Table 2. The status of livestock population by ecological region according to the reports of 1989/1999 as in Fig. 1 shows poultry population higher in the hills, but commercial poultry farms are located in plains and valleys. Poultry farming is the one most successful story of Nepal's transition of animal husbandry (Kaphle, 2000).

Situation of Animal Health Care Systems in Different Ecological Zones

The mountainous regions, ranging in altitude from 4,877 to 8,850 m above sea level, covers

Veterinary Practice in Nepal, Fig. 1 Status of livestock population by ecological region, 1998/1999

35 % of the country. This area is less developed and has only 6.97 % of the country's population. The mountainous topography makes it virtually cut off from other parts of the country; transportation is by foot and on the back of yaks and ponies, although there are some airstrips with irregular schedules. This region has the highest number of sheep, yaks, and chengras (hill goats). The population and economy of the mountain region is based on trade with Tibet and tourism, as well as support from animal husbandry. The demographic distribution is mostly people like the Tamang, Rai, Limbu, Gurung, and Sherpas famous for their mountaineering skills. The pastoral communities have been employing unique ethno-veterinary practices since time memorable. This region has 16 districts and each district headquarters has a government veterinary hospital. A veterinarian supported by junior technicians and some other staff mans these hospitals; their prime duty is to give outdoor health care support, monitor disease outbreaks, and implement and monitor government policy in the related sector. Private practitioners are out of question in these situations where farmers consult veterinarians as a last resort. Traditional veterinary practices like herbal medicines and bloodletting are used for simple cases; however parasites, foot rot, plant poisoning, and microorganism related diseases are

commonly encountered and they respond poorly to traditional medication. The region, with its rough topography and difficult communication networks, has a slow economic growth with livestock, tourism, and herb collection as the only path to greater income. Tourists in this area provide markets for local livestock products. Lack of proper technical and financing institutions with difficult communication and marketing opportunities can be viewed as the obstacles for livestock development. However if successfully harnessed, high altitude animal husbandry will flourish well and the standard of living of the people in this region can be raised substantially.

The hilly region comprises 42 % of the land area and 43.97 % of the total population of the country. This region has some major cities. The livestock health diagnosis aspect of this region is also controlled by the government veterinary hospitals with only a few private organizations and practitioners concentrated in the main cities. The government disease diagnosis mechanism is more concentrated in this region with the location of central veterinary laboratory and major regional laboratories. These laboratories are mainly concerned with large animal diseases and only the central veterinary lab at Tripureshwor, Kathmandu has some facilities for poultry disease diagnosis. This region is making progress, as roads linking to district

headquarters make the flow of goods and people easy and convenient. There are some milk collecting, chilling and processing centres in this region that are boosting dairy farming. As the genetic makeup of the livestock is being improved by upgrading with pure breeding males distributed by government or use of artificial insemination, so is the demand for commercial feed and health care attention. There was an early setback when pure Holstein and Jersey breeds of dairy cattle were introduced, as they could not receive optimum management and nutrition, they developed gynecological and metabolic disorders. Thus government policy has been to see that the genetic make up remains at 62.5 % so that increased productivity and the thriving ability of the animals are enhanced at the same time. The law forbids cross breeding of some indigenous cattle, buffalo and sheep species to preserve genetic composition. Poultry, goat and swine farming are gaining popularity with the effort of private entrepreneurs, government poverty elimination schemes and support of non-government organizations. Co-operatives and villagers' group formations, mainly for women, are encouraged, and facilities for providing loans are adopted to initiate cottage industry and livestock farming. Similarly leasehold forestry projects are implemented in some parts of the region which aim to provide the community a means to use and protect the forest and to help small unit livestock development and at the same time conserve the forest.

The plain region or the terai is the major centre for buffaloes, cattle and poultry. The terai and inner terai accommodate almost 50 % of the nation's population. The plains are densely populated, and migration from the hills and abroad are using up the fertile agricultural land for settlement purposes. There are private practitioners along with the government animal health care system; farmers are educated to a certain extent and like to be in touch with veterinarians for consultation. The supply of western drugs is also bountiful, with many veterinary drug stores located in this region. Farmers sometimes seek

the support of the Indian Veterinary Research Institute (IVRI) and other institutions in India as they have advanced technology for disease diagnosis. This region is developing fast and the livestock industry is making rapid progress. The extreme summer temperature, marketing facility and occasional disease outbreaks are hampering the established poultry and dairy industry. Lack of proper regulation in line with consumers health and public health concerns compounding with transportation to markets in cities is a major hurdle too (Joshi & Oleson, 1999).

History of Animal Disease Diagnosis Pattern in the Country

The government and the private sector both provide animal disease diagnoses. The history of the animal health care system in Nepal is not old; previously traditional health care practices dominated.

The first recorded establishment of a veterinary dispensary at Kathmandu was in the year 1950 B.S (beginning of the nineteenth century in the Julian calendar). In 1940 the present Central Veterinary Hospital was established at Tripureshwor, Kathmandu. The period from 1943 to 1957 saw the establishment of ten veterinary hospitals in different district headquarters of the country. In the year 1964 AD 14 zonal and 19 district veterinary hospitals (DVH), 21 veterinary dispensaries and 18 veterinary check posts were established. With the addition of 25 veterinary hospitals in 1981 and 16 in the year 1984, the country had a government veterinary hospital at all headquarters in the 75 districts. There are five regional laboratories set up to speed up disease diagnosis with special programs for epidemiologically important diseases. There are also regional training centres training farmers on recent techniques of management and primary health care, while selected candidates are given preliminary training to work as auxiliary village animal health workers (LSMP, 1993).

The private sector involvement in this regard is mostly concentrated with the poultry and dairy industry as they are commercially practiced. The share of the private sector in poultry health care is around 60 %, while the government jointly handles the remaining section. The central veterinary hospital and laboratory at Tripureshwor is the most refereed one in the country. It is equipped with modern laboratory facilities and manned by skilled personnel. The district veterinary hospitals and their sub-centres are limited in providing this service. Pet animal veterinarians are based in Kathmandu having their private clinics, while many government vets also have private practices outside their office hours. The military have five veterinarians in their service to take care of stud farms while in the police a single veterinarian looks after the health of the dog squad.

Most commonly encountered communicable diseases of livestock in Nepal are peste des petits ruminants (PPR), rinderpest, foot and mouth disease (FMD), rabies, brucellosis, haemorrhagic septicaemia, black quarter, anthrax, mastitis and swine fever. Infectious bursal disease, Newcastle disease, Marek's disease, infectious bronchitis, chronic respiratory disease and coccidiosis are common poultry diseases. Fasciolosis and infertility are other common diseases of dairy animals (Mathema & Joshi, 2000).

Traditional Animal Health Care Practices in Nepal

Ethnoveterinary medicine describes the traditional practices used by livestock raisers all over the world to keep their animals healthy and productive, and to treat and control diseases (Mathias, 1996).

Ethnoveterinary medicine is an effective means to safeguard the health of animals and the interests of the poorer communities around the world. Poverty and remoteness prevent access to conventional animal health care. To counter this, traditional animal health care has been reborn and now plays a greater role in the lives

of poor farmers. Traditional animal health care is cheap, readily available and safe for poor livestock keepers, but lack of information on its scientific validity, lack of policy support, and the negative attitude from modern veterinary practitioners has until recently limited its promotion. Ethnoveterinary practice in Nepal is a blend of Tibetan and Indian practices. The medicinal plants in the Himalayan range that stretches across the whole length of the country and the diverse ecological conditions have provided suitable grounds for traditional animal health care practices. Adding to that process was the late exposure of the nation to the outside world (~1950s), the fact of having no history of colonization and snail-paced industrialization of animal farming. All these shielded traditional animal health care knowledge from being overwhelmed by Western medicine. However, in recent times, with poultry and dairy farming using advance rearing practices, ancient ways are frowned upon. The consequences of Western medicine misuse in animal production from elsewhere in the world has yet to be learned by the Nepalese industrialists. However, there is a rising awareness to preserve ancient knowledge in the art of traditional animal health care. Encouraging the use of ethnoveterinary medicine, or preventing misuse of Western practices, is part of an important policy for the non-governmental agencies working with their international counterparts in the field of poverty elimination. Restrained if not total ban in use of chemical pollutants in the communities around the vicinity of wildlife reserves is gaining momentum. Nepal is at a crossroads, deciding whether to subsist in the safe ancient way of animal health treatment or to industrialize animal husbandry to meet the growing food challenge and leave the consequences for generations to come.

Animal husbandry is rapidly changing from the traditional system to an industrial form. There are ample opportunities for its growth, as it is deemed the only option for over 80 % of the national population. The small farmers relying on age-old traditional agricultural practices will not

be in a position to compete with cheap products from India, China and elsewhere. Tourism, a major source of foreign exchange, is also seeing its worst days with international terrorism. Thus with no other clear options available, livestock enterprise is making progress. The animal health care system is also making progress, but the speed is much slower. With around 400 veterinary doctors and slightly more junior technicians, the country is not able to meet its requirements. The Institute of Agriculture and Animal Science (IAAS), the only agriculture college, has started to produce around 25 veterinarians per year which is partially filling the growing demand. The lack of infrastructure and other factors makes the level of education below the global level. With advanced training to faculties and infrastructure development the future of the veterinary school at IAAS is bright. Research activities with the limited resources available have been a trademark of IAAS, and it will only get better. Some works on buffaloes (Dhakal & Salman, 1992) and poultry (Kaphle, 2000) have to great extent helped the farmers gain confidence and will to invest and upgrade their animal production activity. Commercialization of animal husbandry and increase in farmer's awareness will make animal health care an important factor, as can be evident from the hustling activities around IAAS, Chitwan. Thus, the nation needs to set up strict guidelines and regulations in implementing the policy of animal health care practices. At the same time, making service available to all the community at an affordable price and in a sustainable way should be the priority of the government (Lin et al., 2003). There should be a mandatory flow of information regarding epidemiological reporting from the field level to the concerned authorities and a rapid execution of appropriate steps. The reckless import of vaccines from foreign countries and reckless use of medicines like antibiotics and hormones should be controlled and a governing authority should look into the necessary criteria. Emphasis should be given to the preparation of vaccines from the local strain of pathogens within the country. Basic laboratory facilities should be developed for disease diagnosis in all district veterinary

hospitals. The school of veterinary medicine and animal science at Institute of Agriculture and Animal science should be strengthened. The manpower development program as well as faculty and student research activities should be initiated. One research area that has the potency to be of great use not only to Nepal but to the whole world is the research of medicinal herbs for various animal healthcare. Hence, in spite of the huge resources in form of traditional ethnoveterinary practice and bountiful medicinal plants, Nepal still needs to pull up its socks to learn from success stories of others, Taiwan being an ideal example (Kaphle et al., 2006).

Village Defenses in South India

Barry Lewis

Department of Anthropology, University of
Illinois at Urbana-Champaign, Urbana, IL, USA

Defense is an inherently reactive process. Given perceived threats to some valued entity or resource, one assesses the strength, technology, and probable tactics of these threats and then works to counter them. In the defense of premodern villages, the whole gamut of human, animal, and spiritual forces that acted on a village's well-being may be reflected in the built environment and the patterns by which the village arranged itself on the ground.

History shows that the simplest defense for the inhabitants of many small communities was to run away. Often effective, it left little, if any, trace in the archaeological record. The most enduring and visible archaeological evidence of village defense typically rests in walls, gates, towers, and ditches that protected a community from other people. The scale of such works tended to be proportional to the size and wealth of the community that built them. However, no village possessed the necessary means – weapons, training, manpower, leadership, and stores – to deal with extraordinary threats such as invading armies or regional famine. Faced with extreme dangers to its well-being, villagers could only submit or flee.

In South India, thousands of villages endured chronic threats to their peace and safety during the Early Modern period, or roughly between CE 1500–1800. The Vijayanagara Empire, which controlled most of India south of the Krishna River, began to collapse in the mid-sixteenth century. The ensuing political instability created an opportunity for other Indian and foreign powers to compete for control of the South. Local rulers and chiefs declared their independence from greater kings and contested similar claims made by their neighbors. Winners and losers alike often turned to plunder and they, along with marauder bands, laid waste to towns and villages in their path.

General patterns of Early Modern village defense in South India can be reconstructed from a wealth of archaeological and historical evidence. These patterns differ across South India's three major geographical divisions: the central plateau or *maidan*, much of which is semiarid scrub jungle; the rainy, forested mountains or *malnad* that flank the *maidan* to the west; and the coastal lowlands that border the Arabian Sea and Bay of Bengal.

Maidan

Maidan villages were among the most consistently fortified small communities of Early Modern South India. Although hill ranges covered in dry forest break its relief, much of the region is good country for cavalry. Throughout history, invading armies often chose it as a natural line of advance into the South. Robber bands also appreciated its many opportunities for looting, cattle lifting, and the relative ease of a getaway.

Each village typically comprised two main parts, a settlement core and the outlying fields and pastures. The settlement core contained homes, the temple of the main village deity, threshing ground, and storage facilities for grain, firewood, and animal fodder. Fields and pasture lands lay between the settlement core and the village's outer limits. The latter were defined by marker stones and posts, as well as by the shrines of lesser gods who guarded the village's ritual boundary. Beyond this boundary, and effectively beyond the village, lay the ritually unclean space that contained the village cemetery or cremation ground. Out there, one also found evil spirits, diseases, and ill fortune, all of which had been driven away by the village gods.

A thick bound hedge fence often surrounded the settlement core and acted as a village's first, if sometimes its only, line of defense. The bound hedge was a densely planted barrier of bamboo, prickly pear, and other plants selected for their thorns and other unpleasant characteristics. It was cheap, fast growing, easy to maintain, and effective against many animal and human threats. Gates guarded by village watchmen covered

roads into the village where they pierced the fence.

The main drawback to bound hedges was that they were inadequate to stop a large and determined attack. To supplement bound hedges, some small villages also chose to defend a strategic point, typically a tower or *hude*, within or near the settlement core, from which villagers threw stones and other missiles at their attackers. Often combined with a bound hedge, the *hude* gave village defenders the tactical advantage of high ground at relatively low cost. Nevertheless, the *hude* defense worked best, or perhaps only worked at all, if one's attackers were simply marauders for whom success was a quick raid and few casualties.

Larger or wealthier villages would defend a perimeter, either drawn around the oldest residential area and village deity temple compound in the settlement core or constructed adjacent to the village's living area. They fortified this perimeter with walls, bastions, and covered gateways made with mud, rubble, and locally quarried stone. Approaches to the village walls were protected by deep, wide ditches and, farther out, by bound hedge fences. Some villages worked the *hude* into their fortification plan. Other villages achieved the *hude*'s advantages of elevation by incorporating nearby isolated hills into their defensive works.

Malnad

In the rainy, forested mountains and deep valleys of the Western Ghats, which separate the central plateau from the coastal lowlands that border the Arabian Sea, village defenses differed fundamentally from those of the maidan. *Malnad* villages were commonly collections of neighborhoods scattered over a large area. Village ritual boundaries were similarly dispersed.

Many *malnad* villages depended for security on their relative isolation and the natural defensive strengths of the region's rugged terrain and dense forest cover. Rather than attempt to enclose one's village within walls dotted with bastions

and towers, *malnad* defenses focused on the lines of communication that led to the village. The reasoning appears to have been that if an attacking force could not reach the village, then it could not harm it.

Exploiting the *malnad* terrain as a potential force multiplier, the passes, roads, and trails that led to a village were defended in depth by earthworks, barriers, and breastworks collectively called *kadangas*. Many of these works were further protected by deep ditches, often filled with thorn bushes. Potential village threats would be confronted along the lines of communication and the village to which these lines led might appear to be essentially undefended. Should the defenses fail, the final option was always to scatter into the forest and return after the threat had passed.

Coast

Most of the rivers that drain South India's central plateau flow east and empty into the Bay of Bengal. The geographical transition from the maidan down to the coastal lowlands is through the Eastern Hills, broken ranges of low hills sparsely covered in patches of dry forest. Villages in the valleys, passes, and lower slopes of the Eastern Hills were laid out like those of the maidan region and were defended by bound hedge fences, walls, towers, gates, and ditches.

Beyond the Eastern Hills, the villages on the broad coastal plain and river deltas were as compact as found in the maidan, but they typically lacked defensive features. The East Coast villages were laid out in an open plan with houses aligned along regular streets. For the inhabitants of these villages, defense often meant scattering into the countryside or seeking the protection of nearby fortified towns.

On the other side of the peninsula, the high mountains of the Western Ghats reach nearly to the Arabian Sea. The lush, wet, coastal lowlands occupy a narrow strip of shore that reaches its maximum extent in the far south. Throughout this region, villages were dispersed entities – groups

of households in a loosely circumscribed locality – that more closely resembled malnad villages than the clustered communities of the maidan and East Coast.

West coast villages also took a different approach to defense. No attempt was made to defend the village per se or its lines of communication. Here, defense centered on individual household compounds, each of which was hedged around by mud or stone walls or a fence of bamboo and thorns. Gateways through these walls were also sometimes reinforced with guardhouses.

Wang Chong

Fabrizio Pregadio

The Chinese philosopher Wang Chong was born in Shangyu (modern Zhejiang) in AD 27. According to his biographies, he came from a poor family and devoted most of his life to teaching, but also held minor posts in the state administration. Later he retired to compose the work by which we know him today, the *Lunheng* (Balanced Discussions). This extensive treatise in 85 chapters (1 of which is lost) was completed in AD 82 or 83, about 15 years before the author's death.

Wang Chong lived about one century after Confucianism had emerged as imperial ideology. In this process, the “rationalist” and socially minded philosophy taught by Confucius had been integrated with cosmological doctrines extraneous to the letter of his teaching. The school of thought to which Wang Chong belonged propounded, on the contrary, a reading of the classic texts devoid of esoteric interpretations.

In his work, Wang Chong analyzes, with a strongly skeptical and even iconoclastic spirit, ideas expounded by earlier thinkers and beliefs shared by the people of his time (e.g., the recourse

to divination, the belief in ghosts, the search for physical immortality, and the idea of an individual spirit that persists after death). Wang's typical procedure is to bring out contradictions in the anecdotes and accounts that he first quotes in full. Through an exemplary logical method, he often does not hesitate to take as true one detail that he has previously refuted, if this may serve to invalidate a different detail.

Philosophically, Wang Chong maintained that all phenomena arise spontaneously, and are not expressions of Heaven's will. Related to this was his opposition to the belief in prophecies and portents, through which Heaven was deemed to legitimate or censure rulers, and assent to or dissent from their policies. While Wang Chong rejected the blend of these forms of esoterism with Confucianism, he fully accepted the metaphysical and cosmogonical doctrines traditionally placed under theegis of Daoism. In this way, he anticipated some of the new developments in post-Han Confucianism.

Wang Xiaotong

Ang Tian Se

There is no record of Wang Xiaotong's early life nor his year of death. We estimate that he flourished from the second half of the sixth century to the first half of the seventh century. The little we know of him is from a memorial he presented to Emperor Gaozu of the early Tang dynasty (A.D. 618–906) on the occasion of the submission of his mathematical text to the throne. The mathematical text he submitted was known as *Jigu Suanjing* (Continuation of Ancient Mathematics) and was subsequently selected as a prescribed text for imperial examinations in A.D. 656. In his memorial, which is now attached to his mathematical text, he mentioned that he had studied mathematics from a very young age. He studied the *Jiuzhang Suanshu* (Nine Chapters in Mathematical Art) thoroughly and had great admiration for Liu Hui's in-depth commentary on the text. On account of his mathematical acumen, Wang Xiaotong was appointed as an instructor in the Department of Mathematics, and later as a deputy director in the Astronomical Bureau. In A.D. 623, together with Zu Xiaosun, an official of the board of Civil Office, he was appointed to re-examine the adequacy of the current calendar.

Composed by Fu Renjun and promulgated for use since A.D. 619, the calendar had on several occasions been found to be losing accuracy in the predictions of solar and lunar eclipses. Based on the structure of the Kaihuang calendar composed by Zhang Bin of the previous Sui dynasty (A.D. 581–618), Wang Xiaotong

criticized the adoption of the *ding shuo* method and the precession of equinoxes in the current calendar. The critique sparked a 3-year debate between Fu Renjun and Wang Xiaotong, culminating in a submission of a proposal for rectifications consisting of more than 30 errors to the Astronomer-Royal. This does not necessarily reflect Wang Xiaotong's achievement in calendrical science. On the contrary, his view of adhering to the traditional model without taking into consideration the uneven apparent motion of the sun and the precession of equinoxes in calendrical calculations was a retrogressive one. His contribution lies in mathematics.

From the late Han dynasty in the first century onward, Chinese mathematicians were familiar with quadratic equations and their solutions. But it was not until the appearance of the *Jigu Suanjing* that equations of the third degree were presented. They arose because of the special needs of engineers, architects, and surveyors of the Sui dynasty. There are 20 practical problems in the *Jigu Suanjing* consisting of a problem (No. 1) on calendrical calculation, 6 problems (Nos. 2–6 and 8) on engineering constructions, 7 problems (Nos. 7, 9–14) on the volume of granaries, and 6 problems (Nos. 15–20) on right-angled triangles. The solutions of most of the problems involved equations of the third degree. For example, problem No. 15 says: "There is a right-angled triangle, the product of two sides of which is $706\frac{1}{50}$ and whose hypotenuse is greater than the first side by $36\frac{9}{10}$. Find the lengths of the three sides." Wang's solution amounts to the formation of the cubic equation as follows:

$$x^3 + \frac{S}{2}x^2 = \frac{P^2}{2S},$$

where P is the product and S the surplus. As a matter of fact, most of the problems in the last three categories involved the use of the equation

$$x^3 + Ax^2 + Bx = C,$$

where A , B , and C are positive numbers. Wang Xiaotong provided the rules for the arrangement

of the equations in all these problems but did not explain the procedure for arriving at such equations. He also did not discuss the equations of higher degrees. Numerical equations of degrees higher than the third degree occurred first in the work of ► [Qin Jiushao](#) around A.D. 1245.

- studied on his own since his youth. Despite both poverty and illness, Wang made unremitting efforts to observe the heavens, calculate planetary positions, and write about astronomy.
- Beginning in the late Ming Dynasty, Western astronomy had been disseminated intermittently into China, and subsequently it was adopted by the Qing (1644–1911) rulers. In 1646, a number of astronomical treatises, earlier written or translated by Western missionaries serving the Ming court, were published together by order of the Qing emperor under the general title *Xi Yang Xin Fa Lin Shu* (Astronomical Treatises of the New Methods of the West, 1646). Unfortunately, the “New Methods” introduced by the missionaries did not reflect the advanced achievements of modern astronomy in seventeenth-century Europe. Even worse, there were some defects and internal contradictions, especially in the parts dealing with the cosmological theory of planetary motions.
- In his *Xiao An Xin Fa* (New Method of Xiao’an, completed in 1633), Wang argued that all of the Western techniques could be reconciled with classical Chinese schemes and therefore could be used to revive the lost traditional astronomy of ancient China. By means of trigonometry, which was not used in traditional Chinese astronomy and mathematics, Wang created a series of methods to calculate ecliptic positions and predict planetary occultations. Forty years later, in his *Wu Xing Xing Du Jie* (On the Angular Motion of the Five Planets, completed in 1673), Wang criticized the contradictions in the *Xi Yang Xin Fa Li Shu* and proposed instead his own model of the planetary motions which differed from both the Aristotelian-Ptolemaic and the Tychonic geostatic models. In addition, he attributed the planetary motions to an attractive force radiating from the outermost moving sphere (i.e., the *primum mobile*). Wang also suggested that there were planets inside the orbit of Mercury which might account for the appearance of sunspots. All of these thoughts, along with some of his methods, were heuristic and had considerable influence on his successors.
- In general, Wang was one of a few pioneers who responded to Western science by

Wang Xichan

Liu Dun

Chinese Academy of Sciences, Institute for the History of Natural Science, Beijing, China

Wang Xichan (July 23, 1628–October 18, 1682), sometimes known by his literary name, Xiao’an, was from Wujiang, Jiangsu province, China. When he was 16, the Ming Dynasty (1368–1644) collapsed and the door to social advancement through the imperial examination system was suddenly closed. After several unsuccessful suicide attempts, Wang abandoned his hopes for an official career and became one of the most distinguished Ming loyalists in his area. He seems to have survived by teaching literature, although his main interest was in astronomy, which he had

conscientiously studying it; he was open to critical acceptance of its major ideas when suitably reinterpreted for use in seventeenth-century China. Nevertheless, some of Wang's arguments were clearly exaggerated. For instance, he assumed that Western astronomy had in fact originated in ancient China, but such claims were due to his radical nationalism and traditional reluctance to recognize any innovations from the West.

- the rockets also had a great cultural value in the Indian Hindu community during festivals like *Diwali* (festival of light).
- From the perspective of modern rocketry, the self-propelled mechanism is considered to be the most essential feature for differentiating rockets with any other nearby forms like arrow-assisted rockets popularly known as *Tir-a-Hawai* or *Agni-Bana* (fire arrows) used in the Indian continent (Iqtidar, 2004). The well-documented use of rockets in Indian warfare is listed during the time of Mughal Emperor Akbar (1556–1605). Rockets became an indispensable weapon in his artillery. One such rocket of the late seventeenth century is preserved at Victoria Museum, Kolkata (Dataa, 1986). This cylindrical rocket with a smooth orifice at the end has an outside diameter (O.D.) of 5 cm and length of 25 cm with a bamboo pool of 125 cm length for guidance during the flight. The shape of the rocket at the middle was slightly reduced in diameter. Mughal rockets were basically of two different types known as *kahak ban* and *Chandra ban*. However, the origins of these rockets are not entirely clear. They might have been a native invention with superior knowledge in the gunpowder alongside with the rich metallurgical background of caste-based India or a technology transfer from China, Mongol, or Muslim empires in the West. Such innovation was widespread for centuries afterwards among the military strongholds of different states in India taking the forefront of rocket weapon in the world. F. H. Winter (1979) listed the use of war rockets in Adhadanagars, Mysore, Jaipurs, Rohillas, Rajputs, Sikhs, Golcondans, Vijaynarans, Polygars, Vairagis, Marathas, Naga Sannyasis, and Bengal covering a vast geographical boundary of India.

War Rockets in India

H. M. Iftexhar Jaim¹ and Jasmine Jaim²

¹University of Maryland, College Park, MD, USA

²The University of Nottingham, Nottingham, UK

The history of war rockets in India raises debates about the exact time of its use and origin due to its presence in the popular myths dating back to the twelfth century (Haridas, 1963), lack of scientific documentation, and clear description of different firing projectiles. Apart from their military uses,

The tactical use of the rockets was focused on to create fire targeting the opponent's ammunition storage from distance unachievable by other means, panic against the progressing army, giving signals, and to destabilize the elephants, horse, or bullocks in the midst of commotion and flash fires (Jaim & Jaim, 2011). Both the British and French military had to face unfamiliar rockets from the mid-eighteenth century in Indian territories. In the first significant victory of the British East India Company in Bengal in 1757 at

Plassey, English soldiers encountered rockets from the Bengal side. With the passage of time, superior weapons in terms of accuracy and reliability dimmed the role of rockets in Indian warfare, which were mostly replaced by canons and guns – a sort of Western influence – and military exchange with the Islamic civilization. However, the southern state Mysore (in modern Karnataka state) revived the massive use of rockets in Anglo-Mysore wars with great decisiveness accompanied by desired control over propulsion. The greatest military feat by Indians using rockets, both historically and strategically, was inflicted by the king of Mysore, Tipu Sultan. Renowned for his bravery and boldness against the British expansions in the late eighteenth century, Tipu was considered to be the biggest enemy by the British in India and was known as the tiger of Mysore. Mysore was crucial for the British colonial expansion in India because of its strategic and economic aspects.

For several decades the British had to struggle with rockets in the hilly, rocky, and marsh battlefields during monsoons in the Seringapatam fort and nearby regions. It was a military necessity to deploy rockets because of the battlefield's topology, heavy canons of that time, and the mobility of troops. Both in-line attacks on the front enemy line and in ambushes, the Indians used wheeled rocket ramps firing 5–10 rockets almost simultaneously (Jaim & Jaim, 2011). Depending upon the target with a maximum range of 2.4 km, specific diameter-sized cylinder and angle of launches were selected. Rockets turned out to be the master weapon in the battle of Pollilur in 1780 in the second Anglo-Mysore war. They created trauma for the British troops as described by the various narratives of British officers. Even Colonel Arthur Wellesley, who defeated Napoleon at the Battle of Waterloo, suffered devastatingly in 1799 during the fourth Anglo-Mysore war; this also shows the inability of the British against rockets even facing it for decades. The swords attached to these rockets created enormous injury and terror by flipping around while landing due to the imbalance of the decreasing thrust and weight. These rockets survived even the

War Rockets in India, Fig. 1 Mysore war rocket at Firepower, The Royal Artillery Museum, Royal Arsenal Woolwich, London

War Rockets in India, Fig. 2 Mysore rocket, zoomed in

moisture of the monsoon season during two Anglo-Mysore wars because of their excellent gunpowder contents and compact sealing. Tipu's army had 5,000 rocket men and his father Hyder Ali had over 2,000 rocket men in their infantry with camels or horses for carrying them.

These wars and use of rockets are well documented, and specimens are preserved at Firepower, The Royal Artillery Museum, Woolwich, London (Fig. 1). Although there are only few surviving specimens of rockets of these kinds, variations are found in their sizes, weights, guiding stick lengths, and design features showing chronological development. These rockets were superior because they used metal in the rocket tubes instead of the boards or paper used in Europe, and they had better gunpowder. Soft iron metal cylinders ensured higher density of the gunpowder as explosives. It also reduced the chance of failures or breaking up in the middle of their flights. Multiple nozzle holes were pierced for propulsion to gain the reactionary force created by the burning explosives. Guidance and aerodynamic stability were ensured by different lengths of bamboo or steel like rods. One specimen had a metal cylinder of 5.8 cm O.D. $\times$ 25.4 cm long with 1.02 m long sword blade attached at the end, and another one had 3.7 cm O.D. $\times$ 19.8 cm long with 1.9 m long bamboo pole. These rockets weight around 2 kg (Narasimha, 1985).

War Rockets in India, Fig. 3 Mysore rockets displayed at Firepower, The Royal Artillery Museum, London (Photo by the author)

War Rockets in India,

Fig. 4 Mysore rocket man in late eighteenth century by Robert Home (Used with the kind permission of the Victoria and Albert Museum, London)

The fascinating fact of these advanced rockets is that these were not made by scientists or engineers. In fact most of these rocket artisans were illiterate, lived in a caste-based society in a closed community, and had no documentation of their recipes regarding them as secrets. It is believed that these productions were state sponsored and most probably developed within the fort area. The knowledge was orally transmitted to the next generation of artisans. This is a sharp contrast with Europe where patents and advertisement of firearms and other technologies were all over the competitive market. However, there were several military manuals like *Fathul Mujahidin* (The Triumphs of Holy Warriors) used by Tipu's army where chapters of rockets discussed their deployment techniques and organizations in the battlefield.

The glorious Mysore rockets ended with the defeat of Tipu Sultan in 1799. Rockets were still around India and appeared during the Sepoy Mutiny of 1857–1858 at Jhansi. Perhaps the restriction of military weapons and ammunition, except for the British and her allies, and their lack of sponsorship or need caused their gradual extinction (Fig. 2).

There had been efforts by Sir William Congreve to study these Indian rockets methodically and to sell them to British army and East India Company as a contractor (Werrett, 2009). Congreve rockets were not that accurate and decisive compared to Mysore rockets as was shown during the Napoleonic wars. The most famous one is the Anglo-American War of 1812 on Fort McHenry, near Baltimore, which inspired poet Francis Scott Key to write the “Star Spangled Banner,” later adopted as the US national anthem. Afterwards, following the impacts of Congreve rockets, rocket units appeared in most of the European and US militaries. The Indian rocket is an amalgam of rich military history and a story of technological diffusion throughout the continents across the globe. Moreover, it shows the superior nature of military weapons in a preindustrial society relying upon illiterate castes in India and opens the scope of reexamination as to whether the imperial power taught superior technology in the early industrial revolution to its colonies or whether it also benefitted from traditional innovations (Figs. 3 and 4).

Water in India: Spiritual and Technical Aspects

Kamla Nath Sharma
AquaWisdom, New Delhi, India
International Commission on Irrigation and Drainage (ICID), New Delhi, India

The content of the Vedas is astonishingly scientific, although much of it remains to be interpreted correctly. Knowledge of the Vedas is synonymous with knowledge of the science and metaphysics of creation.

The subject of water has been treated spiritually, philosophically, cosmologically, medically, and poetically in the ancient Indian literature comprising the *Veda(s)*, *Brāhmaṇa(s)*, *Upaniṣad(s)*, *Purāṇa(s)*, and *Smṛti(s)*. Water is regarded as the primordial substance from which the material universe came into being. Water occupies the highest place among the five gross basic elements of nature, called *pañcamahābhūta*. These are *ākāśa* (earth, substratum, space), *vāyu* (air), *teja* or *agni* (radiation, energy, or fire), *āpa* (water), and *pṛthivī* (Earth). These five *bhūta* constitute the physical

universe. Air is said to have been generated from space, fire from space, water from fire, and earth from water. Fire and water, which are said to pervade the entire universe, have a close nexus and are believed to possess procreative powers (Narayanan, 1995). The tripartite nature of *agni* has been connected with the three forms of water – celestial, atmospheric, and terrestrial, called by different synonyms in Sanskrit so that they have characteristics and attributes responsible for different cosmic, atmospheric, or terrestrial actions.

In the social and religious traditions of India since Vedic times, water has enjoyed a unique status. Water is the single most important tool/ mode for performing daily religious rituals or social ceremonies and a primary means for purification of body and soul in Hindu culture.

From birth till death in a Hindu society, water remains an essential ingredient in performing all rituals.

Vedas and Their Chronology

The time periods of various Vedas are as follows:

<i>R̥gveda</i>	6500–3100 BCE
<i>Sāma Veda</i>	3100–2500 BCE
<i>Yajur Veda</i>	2500–2000 BCE
<i>Atharva Veda</i>	2000–1500 BCE

An organic chronological development in India from 6500 BCE has been suggested (Frawley, 1994), taking into account both Vedic literature and recent archaeological findings.

6500–3100 BCE	Pre-Harappan (early Rigvedic period)
3100–1900 BCE	Mature Harappan (period of four Vedas)
1900–1000 BCE	Late Harappan (late Vedic and Brahmanic period)

The Myth of Aryan Invasion

For the past hundred years or so, Mortimer Wheeler’s hypothesis of “swashbuckling,

Water in India: Spiritual and Technical Aspects, Fig. 2 Harappan sites in Northwest India (Kalyanaraman, 1998)

of Harappan and Sarasvatī civilization sites. According to archaeologist Bisht, before the mature Harappan stage, many regional cultures such as Amri, Kot Dirji, Kalibangan, Dholavira, and Lothal had coalesced into the cultural umbrella of Harappa. They were bound by common economic compulsions and cultural ethos. The site of Dholavira is an excellent example of a Harappan city that tells the history of early, transition, mature, late, and final phases of the Indus-Sarasvatī (Harappan) civilization in India (ca. 3500–1700 BCE). The site spreads over an area of 100 ha. This compares well with the size of Harappa, Rakhigarhi, or Ganveriwala. All this evidence has proved the invasion theory to be unfounded, showing that the Aryans were the native Indians, having an unbroken chronology of civilization.

Place of Water in Ancient Indian Literature

Water has enjoyed a high status in the social and religious context of ancient Indian culture. It was an essential medium for performing daily religious rituals and social ceremonies and a primary means for the purification of body and soul. Even after thousands of years, the rivers in India, especially Gangā (the Ganges) and Yamunā, are considered divine and capable of purifying a sinful body with a few drops of their water. *Agni* (fire) is said to be born from the waters. Both water and fire are said to possess procreative powers. Water is considered a mother, while fire is seen as a prolific generator (Narayanan, 1995).

The place of water as a life-giving and life-sustaining element was very high. It was considered a cleanser of sins and regarded as a divine protector. It was addressed by various names – nectar, honey, ambrosia – in prayers. Stagnant water was considered unhygienic.

The cosmic energy is the generator of the universe, the embryo of waters the leader of humans, most virile defender of the human race, it remains ever illuminated by its own radiance and it provides sustenance for its beloved progeny. (RV 3.1.12)

Earth was formerly water upon the ocean of space. (*Atharvaveda* AV 13.6)

Water or the water element had many names in the Vedas and other Vedic literature. It has more than 100 synonyms. These are not synonyms in a strict sense, since they have been used to indicate their different forms/states and contexts. Some names for water are *Ambu*, *toyam*, *vāri*, *jalam*, *āpaḥ*, *bheṣajam*, *udakam*, *salila*, *madhu*, *ambha*, *ghṛtam*, and *kṣīram*. For example, *salila* is a technical word in the Vedas which is different from *āpaḥ* as mentioned in a mantra from *śatapatha brāhmaṇa* (11.1.6.1) which says that *āpaḥ* was indeed *salila* earlier. *Salila* is the primordial state of the universe, when there is nothing manifested.

The *Chhandogya Upanishad* (7.10.1) says that “it is the waters that pervade everything, big or small, the earth, the atmosphere, the heaven, the mountains, gods, men, animals, birds, grass, plants, dogs, worms, insects, ants. All these worldly manifestations are waters indeed.”

Payers of Water

In the ancient Indian literature, there are a large number of prayers seeking benevolence of water. For example, in *Rgveda* the seer prays thus – “The waters, with their source, the ocean, proceed from the midst of the firmament, flowing incessantly, purifying (all things): may the divine waters, whom the thunder-bearing *Indra*, the showerer, sent forth, protect me here on earth. May the waters that are in the sky, or those that flow (on the earth), those in the channels that have been dug, or those that have sprung up

spontaneously, and those that seek the ocean. All pure and purifying, may those divine waters protect me here on earth” (RV 7.49.1-2) (Arya & Joshi, 1997).

The seers in all the four Vedas hail water practically as a form of god and worship it as such, since it was considered life giving. Water has been variously described as “incarnation of god,” “nectar,” and “the protector of the earth and the environment.”

The sages in (Yajur Veda) (Arya, 1999) pray: “O Water, thou art the reservoir of welfare and propriety, sustain us to become strong. We look up to thee to be blessed by thy kind nectar on this earth. O water, we approach thee to get rid of our sins. May the water cleanse the earth, the earth cleanse me. May the holy waters make me devoid of sins. May the waters remove my bad deeds. The waters that kept the Agni (fire) inside them, bless us. The waters that generate all prosperity on earth and heaven and those which dwell in different forms in the atmosphere, those who irrigate the earth, may be those waters be kind to us and bless us. O Water, kindly touch me with thy divine self and establish strength, radiance, intellect and wisdom in me.”

Nature's Forces as Deities

In Vedic cosmology, *pṛthivī* (earth) symbolizes the material base and *dyāvā* (heaven) symbolizes an unmanifested immortal source. Together and between them, they form the *paryāvaraṇa* (environment).

The seer praises Heaven and Earth (*dyāvā pṛthivī*) by saying, “You are surrounded, Heaven and Earth, by water; you are the asylum for water; imbued with water; the augmenters of water; vast and manifold; you are the first propitiated in the sacrifice; the pious (people) pray to you for happiness, that the sacrifice may be celebrated. May Heaven and Earth, the effusers of water, the milkers of water, dischargers of the functions of water, divinities, the promoters of sacrifice, the bestowers of wealth, of renown, of food, of male posterity, combine together” (RV 6.70.4-5) (Arya & Joshi, 1997).

Water stands for all the elements, because it is really a combination of water, fire, and earth, according to the tripartite creation of the gross elements. Water is all pervading.

Waters Regarded as Having Medicinal Powers

The Vedas also mention the medicinal qualities of water. *Rgveda* hails water as the reservoir of all curative medicines and of nectar.

The *Atharvaveda* describes various sources of waters and describes them as dispellers of diseases and as more healing than any other healer. The scriptures believed that waters avert pain and that they are restorative and curing. Wherever waters fall on earth, plants grow. The hymns in *Atharvaveda* (6.23, 24, 57) hail water as possessing medicinal qualities. A hymn in *Atharvaveda* prays for waters to cure “incurable” diseases.

The *Rgveda* (1.161.9) states, “There exists no better element other than water which is more beneficent to the living beings. Hence waters are supreme.” Varuna is a cosmic ruler as well as the deity that dwells in waters, presides over them, and is prayed to for granting strength and virility from waters.

Another hymn from the *Rgveda* says

Ambrosia is in the waters, in the waters are medicinal herbs; therefore, divine (priest), be prompt in their praise. Soma has declared to me, ‘all medicaments, as well as Agni, the benefactor of the universe, are in the waters’: the waters contain all healing herbs. Waters, bring to perfection all disease-dispelling medicaments for (the good of) my body, so that I may long behold the Sun. Waters, take away whatever sin has been (found) in me, whether I have (knowingly) done wrong or have pronounced imprecations (against holy men) or (have spoken) untruth. I have this day entered into the waters – we have mingled with essence – Agni, abiding in the waters, approach, and fill me, thus (bathed), with vigour. (RV 1.23.19-23) (Arya & Joshi, 1997).

According to *Taittareyī Āraṇyaka* (7.3.2), Agni is an antecedent form and sun the later. Water is a compound and lightning is the joining element. *Maitreyī Saṃhitā* further divides water into three places – sky, earth, and mid-region.

Vājasaneyī Saṃhitā describes the medicinal use of waters. “O water, which we have drunk, become refreshing in our body. May you be pleasant to us by driving away diseases and pains.” Like Agni and Vāyu, *āpaḥ* (water) also serves as a purifying agent.

Rivers as Goddesses

The rivers and river waters have been treated with great reverence since ancient times. Traditionally, rivers such as Gangā, Yamunā, or Narmadā are worshipped as goddesses. Every morning and evening, on the banks of the Gangā at Haridwār, there is daily Gangā worship with lighted lamps in the presence of thousands of devotees, traditional holy music, and chants of mantras. The Sarasvatī River was one of the largest rivers in ancient India before 3000 BCE and drained the Sutlej and the Yamunā. By the end of Harappan culture, the Sarasvatī went dry, bringing about the end of Harappan civilization around 1900 BCE. The Vedic texts are replete with references to the River Sarasvatī and the seas.

River Sarasvatī: Myth or Reality?

Whereas the famous River Gangā is mentioned only once in the *Rgveda*, the River Sarasvatī is mentioned at least 60 times. Sarasvatī is now a dry river, but it once flowed all the way from the Himalayas to the ocean across the desert of Rajasthan. Research by Dr. Wakankar has verified that the River Sarasvatī changed course at least four times before going completely dry around 1900 BCE. The latest satellite data combined with field archaeological studies have shown that the *Rgvedic* Sarasvatī had stopped being a perennial river long before 3000 BCE (Giri).

Numerous archaeological sites have also been located along the course of this river, thereby confirming Vedic accounts. The Sarasvatī is now dated long before 3000 BCE. This means that the *Rgveda* described the geography of North India long before 3000 BCE. This shows that the *Rgveda* must have been in existence no later than 3500 BCE.

Water in India: Spiritual and Technical Aspects,

Fig. 3 Archaeological sites along erstwhile Sarasvatī River

Tritium (hydrogen isotope) analysis of deep water samples taken by Bhabha Atomic Research Centre (BARC), India, has provided a broad spectrum dating for the waters of the Sarasvatī River now revealed as groundwater sanctuaries and aquifers. The waters range from 4,000 to 8,000 years BP (Kalyanaraman 1998).

For over 2,000 years (6000–4000 BCE), the Sarasvatī flowed from Bandarpunch massif (Sarasvatī Rupin glacier confluence at Naitwar in western Garhwal). Figure 3 shows the location of archaeological sites along Sarasvatī River. A remote sensing study of the India desert reveals numerous signatures of palaeochannels. The LANDSAT imagery highlights the course of the River Sarasvatī in Punjab, Haryana, and Rajasthan. The digital enhancement studies of IRS-1C data (1995), combined with radar imagery from European remote sensing satellites ERS I/2, have identified subsurface features and reorganized the palaeochannels beneath the sands of the Thar desert in northwestern India (Paik, 2000).

Ancient Weather Science

In the early Ṛgvedic period, the performance of *Yajnas* (sacrifices) as described in Vedic and Brahmanic literature has some scientific basis. These rituals were performed to ensure timely and adequate rainfall for abundant availability of food, thriving of animal and plant life and for overall human prosperity (Sharma, 2002). The *Yajnas* are very closely related to the evolution of the universe, the solar system, human procreation, occurrence of the seasons, rainfall, and life on earth. Several places in the Vedic literature mention that *Yajnas* produce rain which in turn produces food.

The subject of meteorology was dealt with by several ancient sages, including Nārada, Kashyap, Garg, Parāshar, Vasishṭha, Druhin, Brihaspati, Devala, Vajra, Sahadev, and Rishiputra. *Ashṭādhyāyī* (500 BC) by Pāṇini is perhaps one of the earliest post-Vedic works giving information on rainfall measurement and droughts.

The *Arthashastra* (fourth century BC) of *Kautilya* gives information on rainfall distribution in the country as well as the methods of its measurement. Several of the old treatises in the form of *Purāṇas*, such as *Matsya Purāṇa*, *Vāyu Purāṇa*, or *Vishṇu Purāṇa*, dealt with the role of the sun in rainfall. Water science, which was initially based on observations, kept being refined, and in the post-Vedic period from the third century BC to the sixth century AD, many of the earlier hypotheses came to be perfected. *Kautilya* even gave an estimate of the average rainfall in various parts of India.

In Varāhamihira's time, the units of measurement of rainfall were the *pala*, *adhaka*, and *droṇa*. The rain gage was round with a diameter of one *hasta* (18 in., 46 cm) and had marks of *pala*. When it was full, it indicated one *adhak* of rainfall. One *droṇa* means 2 1/2 in. (6.4 cm) of rain. Accordingly to Parashar, the height and diameter of the rain gage should be 8 *angulas* (6 in., 15 cm) and 20 *angulas* (15 in., 38 cm), respectively, and when it is filled to the brim, it measures one *adhaka*. Parashar also gives a method of measuring rainfall on the ground. If it measures four cubits on the ground, it amounts to one *droṇa*.

Ramanathan (1993) described the significance of rituals and *yagnas* (sacrifices) with their cosmic and scientific interpretations in great details. Observations and measurements of wind, clouds, lightning, thunder, rain, solid precipitation, atmospheric optical phenomena, and agricultural meteorology were presented.

Just as the water vapours are carried higher in the form of clouds and are condensed in the presence of cold air existing in the sky, similarly one can reach the height of spiritual progress and can get strengthened due to restraining the breath through Yogic exercise. (YV 23.26) (Arya, 1999).

The uniform water passes upwards and downwards in the course of days, clouds give joy to the earth; fires rejoice the heavens. (RV 1.164.51) (Arya & Joshi, 1997).

O all learned people, fully realise your conduct towards different objects of the universe, know ye the electricity that maintains all beautiful objects, the sun, the invisible matter brought into creation, the invigorating vital airs, thus ye become the utilisers of all objects. Homage to him who knows the science of clouds, and to him who knows the science of electricity. (Yajur Veda) (Arya, 1999).

These hymns give insight into the cloud-seeding phenomenon and occurrence of rains. Various activities occurring in the firmament were well observed and formulated in scientific terms.

The Present-Day Indian Water Scenario

Present-day India has a geographical area of 329 million hectares (Mha) which is about 2.4 % of the world's lands. The country has a population of over one billion which is over 16 % of the world's population. It has 12 major river basins of catchment area more than 20,000 sq km and 48 medium river basins with catchment area varying from 2,000 to 20,000 km². The presence of the great mountain mass formed by the Himalayas and its spurs on the north and of the ocean on the south are the two major influences operating on the climate of India.

Although the average water availability in the country remains by and large fixed, the per capita water availability has been reducing progressively due to increasing population. As against the per capita water availability of 5,300 m³ in 1955, it was reduced to about 2,200 m³ by 1997 and is presently of the order of about 1,545 m³. With the projected population growth, it is estimated that the average availability might be only of the order of 1,140 m³ by 2050. India needs to build storage capacity to the tune of at least 450 BCM by 2050, against the present capacity of 253 BCM.

Major River Basins of the Country

India is blessed with many rivers. As many as 12 of them are classified as major rivers whose total catchment area is 252.8 million hectares (Mha). See Fig. 4. Of the major rivers, the Ganga – Brahmaputra – Meghna system is the biggest with a catchment area of about 110 Mha, which is more than 43 % of the catchment area of all the major rivers in the country. A total potential of 1,869.35 BCM is available in the country as shown in Table 1.

Water in India: Spiritual and Technical Aspects, Fig. 4 Major river basins of India

National Water Policy

The Government of India has formulated its National Water Policy (revised 2012) which is a broad blueprint of the water resources development, priorities, and use in the country.

Festivals Related to Water

The focal point of Hindu social, cultural, and religious rituals has been water. Indian mythology attaches a lot of importance to the bath (*snāna*) which is mandatory for participation in any important religious occasion. A dip in holy rivers is considered an essential part of Hindu culture, especially on specific occasions such as

the solar and lunar eclipses or occasions specified on the basis of specific planetary configurations, which are considered to have a cosmobiological effect on the human body. In a cycle of 12 years, a great Indian festival takes place which is known as Mahā Kumbha or Great Kumbha, where millions assemble and have a dip in the waters of the sacred rivers. Every third year, a smaller water festival called Ardhā Kumbha (half Kumbha) is also held, where people congregate at specified places at the banks of the holy rivers (Sharma, 1998). In the mythological scriptures, it says that the elixir of life, ambrosia (*amṛt*), which emerged from the churning of the ocean by the gods and demons, splashed out of the pitcher and fell to earth at four places: Haridwār, Prayāg, Ujjain, and Nāsik. These are located on the banks of the

River Gangā, at the confluence of the rivers Gangā, Yamunā, and Sarasvatī; on the banks of Shiprā; and on the banks of Godāvarī. A tussle ensued among the gods and the demons for 12 days. During this period, the moon did not let the *amṛt* fall from the pitcher, the sun did not let the pitcher crack, Jupiter protected it from demons, and Saturn saved it from being whisked away. Thus, these four planets, which were responsible for saving the pitcher of ambrosia (*amṛt kumbha*), have become an integral part of the Kumbha. Various astronomical conjugations

during Kumbha represent various stages of the solar cycle which have a direct influence on human beings and the biosphere. The holding of Kumbha at an interval of 12 years is symbolic of the need for purifying the body by sublimating the inherent vices of the 12 sense organs – five organs of action, five organs of perception, and the mind and the intellect – thereby arousing the six psychic centers or *chakra* separated from each other at distance of 12 *angula* (finger widths) for attaining the *amṛt kumbha* or pitcher of ambrosia (Dixit, 2001).

Water festivals are also celebrated in several other ways in North and South India. It is customary to take a dip in the holy waters of rivers on various auspicious occasions.

Water Management and Reservoirs in India and Sri Lanka

Andrew M. Bauer¹ and Kathleen D. Morrison²

¹University of Illinois, Urbana, IL, USA

²University of Chicago, Chicago, IL, USA

Water storage and distribution technologies have played an important role in the histories of southern India and Sri Lanka. Given the variability in rainfall and the relatively dry conditions over much of the region, it would have been difficult for southern Asian agriculture, diet, and cuisine – particularly the heavy emphasis placed on rice – to have taken the forms they did without the historical development of water management techniques. Reservoirs, alternately known as “tanks,” also served important roles as sources of domestic water, stock tanks, and sources of resources such as fish and clay. Moreover, debates about the efficiency, sustainability, and equitability of modern “big dam” projects versus “traditional” methods of providing much-needed domestic and agricultural water continue to dominate Indian politics today. Here, we review historical forms of water management in South India and Sri Lanka, paying particular attention to ancient reservoir systems.

South India and Sri Lanka are dominated by a monsoonal climate, whereby the southwest (or advancing) monsoon generally brings rains between the months of June and October and the northeast (retreating) monsoon in November and December. In addition to monsoon strength, a variety of topographic factors relate to the distribution and concentration of rainfall across the region. Parts of the southwestern and western coasts of India receive between 3,000 and 3,200 mm of rainfall a year due to the orographic (related to, or caused by, physical geography, such as mountains or sloping terrain) effects of the Western Ghats – South India’s most pronounced north–south ranging mountain chain. On the eastern side of the Ghats, however, a rain shadow is created that markedly reduces the amount of precipitation in the central areas

of the southern peninsula. For example, Bengaluru, the capital city of the modern state of Karnataka, receives an average of around 850 mm of rainfall per year, while Hyderabad, the capital of Andhra Pradesh, receives an average of only 700 mm of rainfall. Indeed, much of the area within the orographic rain shadow of the Western Ghats can be considered a semiarid climate, with average rainfall levels falling as low as 400 mm (India Meteorological Department, 1981). Sri Lanka’s topography creates a similar pattern in which the southwestern coastal areas receive the bulk of the advancing monsoon and the northern and eastern coasts – largely in the rain shadow of Sri Lanka’s central highlands – receive precipitation from the shorter, retreating monsoon. However, it is important to note that actual rainfall in all parts of the Indian peninsula and Sri Lanka can show significant intra- and interannual variability as a result of being dependent on the relative strength of the monsoon. All of the rivers of the Indian peninsula and Sri Lanka are ultimately monsoon-dependent, unlike the great northern Indus and Ganges rivers systems which also receive seasonal runoff from Himalayan snowmelt. Thus, rainfall is one of the most important variables influencing agriculture and vegetation across this region.

South Indian and Sri Lankan reservoirs include a range of facilities constructed for the purposes of collecting and storing water, generally for agricultural production. These consist of artificial embankments built across paths of gravity water flow, whether intermittent streams, rivers, or simply slopes that might carry runoff after a monsoon rain. Reservoirs may or may not involve excavation of a basin to contain this water, but they are all storage or storage/distribution devices built on a relatively large scale and meant to contain water behind an embankment or dam rather than within its major construction. In this sense, we make a distinction between cisterns (which collect and store water within a rock-cut or other constructed facility), wells (which tap the water table), reservoirs, and tanks. The term “tank” is widespread in the South Asian literature, indiscriminately used to describe almost any water-holding feature, although the term most

frequently refers either to reservoirs or to temple tanks – large masonry structures that hold water for ritual ablutions and other functions associated with temple worship. Temple tanks often derive their water from the water table. As such, temple tanks and reservoirs are wholly different in construction, morphology, and operation, similar only in their capacities as water-holding devices and in certain parallels of meaning and symbolism (Morrison, 2009, 2012).

Early Forms of Water Management in South India and Sri Lanka

The earliest culturally significant water catchment features in South India were not constructed reservoirs (in the terminology outlined above), but seasonal pooling basins, or cisterns, which developed naturally from the differential weathering of bedrock or, in some instances, were created by quarrying stone basins and pooling sheet flow behind low stone embankments (Fig. 1). In geomorphological terms, these features are known variably as gnammas, rock pools, or weathering pits and are considered to be characteristic features of residual hills and inselbergs – isolated hills composed of resistant rocks (e.g., granite or gneiss) that express pronounced topographic relief from a surrounding plain – throughout the heavily weathered terrain of the tropics and subtropics (Thomas, 1994; see also Porembski & Barthlott, 2000). In South Asia, such basins occur on the granite and gneiss hills that characterize much of the central and southern portions of the Indian peninsula as well as parts of Sri Lanka (e.g., Fernando, 1976). Indeed, because granite and gneiss are particularly impermeable rock types, the bare hills of South India generate large volumes of runoff water during the heavy monsoon months that collects in such depressions.

Water retaining rock pools appear to have taken on cultural significance by at least the Iron Age (1000–500 BCE) in several regions of South India. It is evident from systematic archaeological survey that during this period inhabitants both modified and constructed rock pools to store

Water Management and Reservoirs in India and Sri Lanka, Fig. 1 Sediment filled and abandoned modified rock pool at an Iron Age site in the Koppal district of northern Karnataka (photo by Andrew M. Bauer)

water for human and animal consumption. For example, numerous prehistoric herding sites located on granitic hills in central Karnataka show associations with rock pools, suggesting the landscape features were important to early forms of land use and grazing routines in the region (Bauer, 2011, 2014). It is also important to note that there is a clear cultural association between such rock pools and early mortuary and ritual locations, which were often marked by the construction of megalith monuments. Large concentrations of elaborately constructed megaliths – ranging from dolmen cists, stone circles, rock cairns, platform enclosures, stone spirals, and more – appear to have been deliberately placed adjacent to water basins in many hilltop locations. Perhaps the most striking example of such an association occurs at the site of Hire Benakal in northern Karnataka, where hundreds of megaliths are found near a broad shallow water basin that likely began as a rock pool and was subsequently expanded by quarrying activities for the construction of monuments (Fig. 2).

Additional sites also demonstrate associations between water and culturally significant ritual places. For example, a brick platform structure enclosed by granite boulders at Bandibassappa Camp, also a large megalithic complex in northern Karnataka, appears to have been situated adjacent to a rock pool that was later modified.

Water Management and Reservoirs in India and Sri Lanka, Fig. 2 The site of Hire Benakal, showing dolmen cists on the quarried banks of a basin feature that likely began as a natural rock pool (photo by Andrew M. Bauer)

Water Management and Reservoirs in India and Sri Lanka, Fig. 3 Passage-chamber megalith associated with a modified rock pool at an Iron Age site in the Koppal district of northern Karnataka (photo by Andrew M. Bauer)

Furthermore, systematic documentation by Bauer (2014, 2011) and Bauer and Trivedi (2013) of the area around Hire Benakal suggests that additional megalithic monuments were regularly sited adjacent to ancient water retaining rock pools (Fig. 3). Gordon and Allchin (1955) also reported 80 megaliths at a site near Bilebhavi where they identified two “tanks” (cisterns), one of which was “lined with stone slabs.” They likewise recorded a similar construction on a hilltop megalith site near Koppal (Gordon & Allchin, 1955, p. 99). The association between megaliths and water basins has also been noticed in Tamil Nadu and Sri Lanka (cf. Myrdal-Runebjer, 1996; Seneviratne, 1984), suggesting a ritual importance to water and possibly a sacred dimension to early water management throughout much of the region.

Although rock pools likely served as the earliest water retention features in the region, it is clear that during the Iron Age, humans began deliberately expanding pooling basins and creating them through activities of quarrying, excavation, and the construction of embankments, or bunds. This is evidenced not only at megalithic ritual sites, such as Hire Benakal, but also at settlement sites, where both cobble-lined basins and constructed earthen bunds are present. At the Iron Age habitation site of Kadebakele (northern Karnataka), for example, inhabitants modified

the drainage pattern on top of a granitic hill to form a water catchment basin. Excavations in this reservoir show that it collected and held water for only part of the year, partially a consequence of the reservoir’s relatively small catchment area of 0.027 km². The facility also experienced major drying episodes as well as significant siltation (Bauer, 2014). Nevertheless, it certainly provided much-needed water to local residents at certain times.

It is difficult to say to what extent these early water retention features may have supported cultivation. Most are quite small and lack provisions for water distribution necessary for large-scale agriculture. Moreover, they are often perched atop high hills with little cultivable land. However, some early reservoirs do occur within natural drainage ways, occasionally in association with check dams and at the base of topographic features where seasonal water could potentially be pooled for crop production. In fact, Devaraj, Shaffer, Patil, and Balasubramanya (1995, p. 66) report “interlaced, hydraulically laminated” deposits behind a “rammed” earthen construction near the base of a granite outcrop at Watgal – a Neolithic (3000–1000 BCE) to Iron Age (1000–500 BCE) period settlement site in northern Karnataka. (However, it is important to note that the authors do not identify this feature as a reservoir or attribute it with any water retaining

“function.”) It is difficult to characterize the entire range of variability in form and function of early water management constructions without more systematic work. Indeed, few regions have been systematically studied, and the patterns described above may not hold true across the entire region. Nevertheless, it seems that water retention techniques began to be practiced in a variety of settings during the Iron Age (see also Allchin, 1954). In addition, the development of water management technology during this period generally coincided with the introduction of new cultigens – including rice cultivation – suggesting that water retaining features became increasingly important to agricultural production by the end of the first millennium BCE. At Kadabakele, for example, farmers of the middle Iron Age (ca. 800–550 BCE) grew a suit of dryland crops similar to those used in the preceding Southern Neolithic, but with the addition of water-intensive crops such as bananas and wheat (Morrison, Reddy, & Kashyap, 2014).

In the first millennium CE, there is stronger evidence for the construction of larger reservoirs that were used to meet the hydrological requirements of cultivation. A series of reservoir walls have been reported in the environs surrounding Sanchi – a well-known Buddhist monastic site in west-central Madhya Pradesh spanning the third century BCE to the twelfth century CE. These reservoir features are built of earthen embankments reinforced by stone masonry, with dams reaching nearly 6 m in height and expanding across drainage valleys, in some cases exceeding 1 km in length. Moreover, catchment areas range from 0.74 to 17 km² (Shaw & Sutcliffe, 2001), potentially damming considerably more water than the Iron Age features discussed above. Artifact associations, as well as the proximity of the embankments to the site of Sanchi, have allowed scholars to suggest that several of these features were constructed as early as the second century BCE, while others were built throughout the first millennium CE (Marshall, 1940, p. 13; Shaw & Sutcliffe, 2001).

Although dating features such as reservoir walls remain problematic without direct geochronological assessment (e.g., radiocarbon, optically

stimulated luminescence, etc.) or inscriptional data, textual references from the Early Historic Period (500 BCE–CE 500) suggest that reservoir construction was prevalent in some parts of India, and in South Asia more generally, during this time. For example, Chakravarti’s (1998) analysis of the *Arthaśāstra* – an economic and political treatise composed sometime in the late centuries BCE or early centuries CE – suggests that Mauryan rulers (ca. 324–185 BCE) were concerned with establishing irrigation works. Moreover, numerous inscriptions and textual references indicate that the construction of reservoirs and irrigation facilities underwent remarkable development in Sri Lanka during the Early Historic Period, particularly on the island’s drier north and east sides. Northeast of Sigiriya, the Minneriya reservoir built during the reign of Mahasena (CE 276–303) is particularly noteworthy. This reservoir – fed by a canal as well as surface runoff – consisted of an embankment nearly 2 km in length and at places exceeded over 13 m in height. Inscriptions dated to the reign of Mahasena’s successor speak of “three harvests of [rice] paddy per year,” suggesting a marked impact on agricultural production (Gunawardana, 1971, p. 8).

Middle Period Reservoirs: The “Traditional” System

It should be clear from the above discussion that reservoirs and water storage features have a long history in South India, and South Asia more generally. However, the proliferation of large reservoir construction for the purposes of agricultural intensification is most salient in South India after the Early Historic Period and in Sri Lanka only slightly earlier. Many reservoirs continue to be used, although the expansion of both electricity and deep bore wells has significantly transformed water use across Southern Asia toward greater exploitation of ground as opposed to surface water.

Numerous textual sources clearly indicate that reservoirs played an important role in the Early Middle Period (CE 500–1300). Although small

Water Management and Reservoirs in India and Sri Lanka, Fig. 4 A Middle Period reservoir embankment and sluice gate used to dam a valley below the Iron Age site of Hire Benakal (photo by Andrew M. Bauer)

dam-and-basin facilities for water impoundment continued to be built and used, Middle Period reservoirs typically consist of masonry-faced earthen dams thrown up across valleys, at the base of hills, and in other locations where seasonal runoff and small streams could be captured (Fig. 4) (Morrison, 1993a, 2009). Like the Minneriya reservoir in Sri Lanka, some were supplied by canals, which took off via diversion weirs or anicuts, from perennial rivers or intermittent streams. Water was moved downstream from reservoirs to agricultural fields through masonry-lined tunnels under the embankments, which were regulated by sluice gates (Figs. 5 and 6). Some water was also released over specially constructed waste weirs, facilities which range from boulder-filled cuts to elaborately built spillways (Fig. 7). Although the focus was clearly on the storage and downstream distribution of water, reservoir beds were also sometimes used for cultivation and reservoirs served as important sources of fish, silt and clay, and water for livestock. Reservoirs were also used to raise the water table around them, an important function even when the bed failed to fill. In fact, we have documented a consistent (but not universal) pattern of wells downslope from sluice gates (Morrison, 2009).

Reservoirs were particularly important in the far south, in present-day Tamil Nadu, where many of them were supplied by river-fed canals (Ludden, 1999). There it is possible to see perhaps the greatest elaboration of the so-called system reservoirs – long chains of reservoir facilities that flow one into the other, linking large areas into tightly knit watersheds (Sharma & Sharma, 1990; see also Mosse, 2003). Unfortunately, none of these systems has been specifically analyzed on the ground to determine precise construction sequences, so although we know of many specific single-reservoir projects dating as early as the seventh century CE, we cannot say exactly how the overall system functioned at this time or even how much of the landscape was under reservoir irrigation. It should be noted, however, that Early Middle Period reservoirs, “traditional” by any reckoning, ranged widely in size from very small ponds to vast “seas,” the latter falling well within the contemporary definition of a “large dam (Crest length ≥ 500 m, maximum flood discharge $\geq 2,000 \text{ m}^3 \text{ s}^{-1}$, “especially difficult foundation problems” or “unusual design” (ICOLD World Register of Dams, 1998)).”

Similar to the “systems reservoirs” of Tamil Nadu, large Sri Lankan Early Middle Period reservoirs were linked through vast networks of canals. The Minneriya reservoir, for example, was connected to other facilities via the construction of a “great canal” during the reign of Aggabodhi I (ca. CE 571–604), and composite maps of the irrigation facilities around Sigiriya show that it fed at least two large reservoirs – the Kaudulla and Kantalai reservoirs. Moreover, detailed survey has shown that smaller dam-and-basin features were also probably constructed and maintained throughout the period (Myrdal-Runebjer, 1996). Again, it is difficult to know how the overall systems functioned simultaneously. However, it is clear that Middle Period rulers and elite made demonstrative efforts to construct new irrigation facilities and repair older ones. In fact, the Minneriya inflow and outflow canals were repaired at least several times in the early centuries of the second millennium CE (Myrdal-Runebjer, 1996; see also Brohier, 1934; Gunawardana, 1971).

Water Management and Reservoirs in India and Sri Lanka, Fig. 6 The northern sluice of the Daroji reservoir, south of Vijayanagara. This “double sluice” construction became prominent in the sixteenth century, when the Daroji embankment was constructed. This sluice and reservoir have been maintained and continue to operate (photo by Kathleen D. Morrison)

This pattern of extensive reservoir use in Sri Lanka and the far south of the Indian peninsula contrasts with that of drier regions in the northern interior of the subcontinent (Karnataka and parts of Andhra Pradesh). In these northern regions,

reservoirs were (and are) almost exclusively run-off-fed, and, given lower rainfall, they are generally not as closely spaced as those of the southern Tamil country. Still, many regions saw the use of both system and isolated reservoirs. In the area we have studied in northern Karnataka, reservoirs seem to have been only a minor component of Early Middle Period agricultural strategies. However, by the Late Middle Period (1300–1700), and especially with the expansion of the large but loosely knit empire of Vijayanagara (ca. 1330–1600) across much of the peninsula, reservoir irrigation expanded considerably, especially in the drier zones where it had previously been limited. In and around the eponymous capital city of this empire, urban foundations in the early fourteenth century and the subsequent expansion of settlement and population explosion in the region propelled reservoirs into increasingly important components of larger agrarian and political strategies (Fig. 8). Important from the start of the Vijayanagara period, reservoirs also constituted a key form of agricultural intensification in the sixteenth century, or Late Vijayanagara period, especially in regions where canal irrigation was not feasible (Morrison, 1995, 2001).

Reservoirs played variable roles in the processes of Vijayanagara agricultural intensification and change; this variation was structured as much by political factors and settlement dynamics as by environmental variables such as runoff and soil conditions. What is common to most parts of the urban hinterland, however, is the

way in which the vast majority of reservoirs fell out of use after (in some cases, during) the Vijayanagara period. Very few of the reservoirs from the original system still effectively function, though there are a few notable “living” reservoirs with long histories of maintenance and reconstruction (Morrison, 1993, 1995). For example, the Daroji reservoir, the terminus of one of the largest systems in our study area, continues to collect runoff from a catchment area of 955 km² and provides water for downstream agricultural fields (Fig. 9).

Research on Middle Period reservoirs includes analyses of pollen and charcoal from reservoir

sediments (which allow the reconstruction of fire and vegetation histories), sedimentological studies of reservoir fill and changes to erosional regimes and local hydrology, and stylistic analyses of sluice and embankment construction (e.g., Morrison, 1994, 1995; Myrdal-Runebjerg, 1994, 1996). In addition, we have also considered tens of thousands of textual and inscriptional records describing facility construction and maintenance as well as conflicts over water, land, labor, and rule (Kotraiah, 1995; Morrison, 1995; Morrison & Lycett, 1994, 1997). All of these diverse lines of evidence suggest that Middle Period reservoirs, like their contemporary and

Water Management and Reservoirs in India and Sri Lanka, Fig. 9 *Left:* inset showing ASTER satellite image of the Daroji reservoir, first built in the sixteenth century south of Vijayanagara. Notice the strong growth of agricultural crops indicated by the reflection of near-infrared

wavelengths (shown here in red) downstream from the embankment. *Right:* digital elevation model and modeled watershed catchment area of the Daroji reservoir basin (data originally obtained from NASA)

colonial counterparts (Mosse, 2003, pp. 45–46), were highly unreliable sources of irrigation, especially in more arid regions. Runoff-fed reservoirs, in particular, may fail to fill in dry years; in the drier districts, this meant not only that reservoirs could usually not support wet crops such as rice but also that dry crops such as millets might not be assisted by the facility. The situation was somewhat better in areas of higher rainfall, but everywhere in southern India reservoirs are marked by high evaporation rates, high siltation rates, and ongoing maintenance challenges (Fig. 10). Indeed, early colonial observers noted that in drought years, reservoir-watered fields actually fared worse than solely rainfed ones, although this was clearly an extreme example.

Reservoirs, Politics, and Contemporary Development

Across much of South Asia, contemporary “big dam” projects have been cast as the legacies of

high modernist social and environmental engineering (cf. Gadgil & Guha, 2000; Scott, 1998). In India, well-organized and highly visible social protests have been made against specific projects such as the Sardar Sarovar project and others along the Narmada River. Often, antidam groups suggest that the answer to sustainable and equitable development lies in a return to a “traditional” system of technology and management. It is not our purpose to argue the case for “modern” or “traditional” forms of water distribution. Rather, we wish to suggest that arguments that hinge on the dichotomies of large/small, inequitable/equitable, and political/apolitical that often accompany distinctions between “modern” and “traditional” forms of water management are inappropriate.

The notion that large political dam projects are entirely a product of modernity is decidedly incorrect. This is no clearer than in South India, where some Middle Period reservoirs were created with embankments more than 3.5 km in length and over 15 m in height. As already

Water Management and Reservoirs in India and Sri Lanka, Fig. 10 Photo showing the accumulation of an estimated 2–3 m of silt and clay, to near the top of a sluice gate. This reservoir is adjacent to the village of Avinamodugu, south of Vijayanagara (photo by Kathleen D. Morrison)

noted, the Daroji reservoir in northern Karnataka pooled runoff over a total catchment area of nearly 1,000 km²; however, size alone is not the issue. Both small and large reservoirs were deeply political projects, tied to networks of patronage and power. Middle Period reservoir construction was sponsored by a wide range of political leaders from kings (rarely) to local chiefs (commonly) and was also connected with Hindu temples in a number of ways (Morrison, 1995; Morrison & Lycett, 1994, 1997). Moreover, even during the Iron Age and Early Historic Periods, shifts from a reliance on rain-fed agriculture to reservoir irrigation would have produced a new material order on the landscape that was necessarily related to sociopolitical fields. Indeed, the questions – How was labor mobilized? Who had access to irrigation water? And how was this decided? – are entirely appropriate in examining the entire history of water management. The answers to these questions undoubtedly had sociopolitical ramifications for ancient inhabitants. This may have especially been the case when irrigation accompanied the introduction of new cultigens and cultural values of cuisine shifted. It is not difficult to imagine the profound social consequences of being a dry-farming millet producer/consumer versus a wet-farming rice producer/consumer when rice was a high status cultigen and the preferred donation to Hindu temple gods during the Middle Period, for example.

The above considerations of the (un)reliability and the political nature of historic reservoirs of South India and Sri Lanka are not to suggest that these impressive systems have no contemporary value with regard to (re)developing water management strategies. Quite the opposite is true: work on the 3,000-year history of irrigation in southern India shows both success and failure in equal measure, portents for a reasonably hopeful future. Thus, although there is no simple solution to the water problems of the dry tropics of South Asia, surely an informed perspective on the actual historical experiences of the region must provide a more secure basis for future planning than either a romantic and unrealistic view of “tradition” or a blind faith in “modern” science and technology.

Water Management at Angkor

Dan Penny

Geosciences, University of Sydney, Sydney,
NSW, Australia

What Was Angkor?

Angkor was the capital city of the Khmer kingdom from the latter half of the first millennium AD. At its peak in the eleventh to twelfth century AD, the Khmer kingdom incorporated Cambodia, southern Vietnam, southern Laos, and parts of Thailand. Angkor was the primate city of this vast kingdom and was connected to a network of smaller, satellite cities by an extensive road system (Hendrickson, 2010). King Jayavarman II founded Angkor, it is commonly said, in 802 AD, proclaiming himself the universal king and unifying a constellation of smaller chiefdoms that were grouped by Chinese visitors under the generic names “*Funan*” and “*Chenla*.” However, this date comes from a stone inscription (K235; Coedès & Dupont, 1943–1946) written hundreds of years after the events it depicts, and its veracity is widely questioned (Vickery, 1998). Indeed, many of the early state temples that characterized Angkor’s urban form may be much older than the epigraphic evidence suggests (Penny et al., 2006; Pottier, 1996). Whatever the date of Angkor’s establishment as a city, it likely emerged from a long period of occupation in the area that dates back to the second millennium BC.

No primary historical documents (stone inscriptions in Khmer and Sanskrit) from Angkor are known after the end of the thirteenth century AD. Monumental construction in the capital also ceased at this time. It is not until the late sixteenth century that European visitors – initially Portuguese missionaries and merchants – began to describe Angkor (Groslier, 1958). At that time, the city was in ruin, almost completely abandoned and overgrown with forest. More detailed accounts emerged in the nineteenth century from explorers such as Henri Mouhot – often incorrectly credited with the “discovery” of Angkor in

1860 – and in the subsequent and ultimately ill-fated “Mekong Expedition” of 1866, led by Doudart de Lagrée (Osborne, 1996). The romantic notion of the ruined city conjured in nineteenth-century Europe by these reports from the Far East was, in part, fanciful. Angkor was never completely abandoned by the Khmer, and in fact the city was reoccupied – if only briefly – by a Khmer king in the 1550s. Angkor Wat was probably continuously occupied by Theravāda Buddhist monks, and significant construction occurred in the sixteenth century at Angkor Wat and extensively within the enclosure of Angkor Thom (Jacques, 2007).

Discovery of the Water Management Network

The dense jungle that covered most of the abandoned city hampered the initial European attempts to explore and map Angkor. Even in the earliest maps, however, the significance of hydraulic infrastructure in defining the urban form is clear. By the late 1930s, scholars from the École Française d’Extrême Orient (EFEO), particularly Georges Trouvé and Henri Marchal, were producing maps of central Angkor that revealed an astonishing array of infrastructural elements – canals, embankments, dykes, moats, reservoirs, and ponds – used for trapping, holding, and moving surface waters around the city (Goloubew, 1941; Trouvé, 1933). Moreover, these features are shown to be part of a complex, interconnected network of water management infrastructure, covering a large area. The publication, in 1979, of Bernard-Philippe Groslier’s *La Cité Hydraulique Angkorienne* represents an important point of inflection in the analysis of Angkor’s water management infrastructure, capitalizing as it does on half a century of archaeological excavation and aerial survey undertaken by Groslier and his colleagues from the EFEO. *La Cité Hydraulique* is Groslier’s best known work and the first attempt to consider Angkor’s entire water management system from a functional, mechanistic point of view, even though he had presaged this approach some decades earlier on a

smaller scale (Groslier, 1958). It was also his most unequivocal statement on the role of the water management system in the demise and eventual collapse of the city.

Research on Angkor's water management system ground to a halt during the early 1970s as the Cambodian Civil War gained momentum, forcing the EFEO to flee Cambodia. It was not until the United Nations intervention in Cambodia in 1992 that the EFEO was able to reestablish its research base in Siem Reap and recommence its work. The publication of a comprehensive map of Angkor's central and southern districts by Christophe Pottier (1999) fundamentally changed the known scale and, particularly, the complexity of the settlement matrix, including its water management network. Advances in remote sensing techniques produced increasingly detailed maps of the city, notably the 2007 publication by Damian Evans, Christophe Pottier, and colleagues of the first comprehensive map of the entire city (Evans et al., 2007) and, again in 2013, using laser-based mapping of the landscape below the forest canopy (Evans et al., 2013). These findings represent the culmination of an aerial archaeology program that began in the 1930s. We now know that the water management network incorporates an area of between 900 and 1,000 km², making Angkor the largest preindustrial settlement on Earth. It is the water management network, in fact, which gives coherence to the low-density occupation scattered among it and to the state-level religious and administrative centers. It defines and delineates the city.

Demise, Collapse, and Reuse

Groslier (1979) observed a tendency to create new rather than renovate old water management infrastructure, creating an unwieldy degree of complexity. By the end of the eleventh century AD, he says, all of the natural rivers had been captured and diverted to feed the water management network, and Angkor had reached its carrying capacity in terms of hydraulic infrastructure. Angkor's development from that point would be characterized by the city choking on its own infrastructure.

The scale and complexity of the water management system had two primary implications in Groslier's hypothesis: First, the operation of any one part of the system was directly dependent on many other parts, meaning that even relatively small changes (such as a particularly wet year or the infilling of one important canal) can trigger a catastrophic failure across the entire system. Second, the trapping of surface water within the water management system encouraged the sedimentation of suspended silt and clay, along with the nutrients that adsorb to them. While initially beneficial to rice agriculture, long periods of stagnation in a large network effectively stripped the nutrients from the irrigation water. The consequence was to accentuate problems of siltation "upstream" while starving nutrients from receiving fields "downstream." He also argued that drying of rice fields, presumably a result of failures in the irrigation system, resulted in the oxidization of mobile iron in the soil, creating a hard and sterile base that further compromised the productivity of rice fields.

The comprehensive maps of Angkor's water management system identify numerous instances of apparent failures in the network – canals breaching their banks or cutting through or around embankments and bridges (Evans et al., 2007; Pottier, 1999). The well-known example of "Spean Thma" (stone bridge), which crosses over an N-S canal to the east of Angkor Thom, has become emblematic of the degeneration of the water management network. In that case, the post-thirteenth-century bridge was partially destroyed as the canal – now the Siem Reap River – eroded several meters into its bed (Kummu, 2009). Further downstream the soil from this erosion filled major canals linking Angkor with the Tonle Sap Lake (Buckley et al., 2010). It is clear that, by the fourteenth century, Angkor's water management network was suffering from numerous problems that were not or could not be rectified. Some have argued that the water management system created a kind of "inertial force" for the people of Angkor (Fletcher et al., 2008). It was too large and too complex to remove or reconfigure, forcing communities and the administration to deal with the strangulating legacy of redundant or inefficient

infrastructure – the product of hundreds of years of intensive water management. As Groslier (1979) put it, “they had hardly any choice: once they had adopted their course of action, they found themselves as if dragged down the slope without any power to stop themselves” (p. 191).

The degeneration and eventual failure of Angkor’s water management system in the fourteenth and fifteenth centuries is coincident with severe drought (Buckley et al., 2010), which caused significant social upheaval throughout Asia (Lieberman & Buckley, 2012; Sinha et al., 2011). The most severe droughts during this period occurred between approximately 1350–1370 and 1400–1420 AD, punctuated by an unusually wet period in the last decades of the fourteenth century. Much of the physical evidence for problems in the water management system dates to this period of dramatic instability, suggesting that climate may have been the specific trigger for the collapse of the water management network and the abandonment of the city by the elite. It is clear, however, that Angkor’s remarkable vulnerability to climatic variability was created by the size, complexity, and rigidity of its urban fabric and, particularly, its water management system.

Parts of the Angkor’s water management system still operate today. Alterations to the system during the 1940s allowed water to flow once more into the West Baray reservoir, which now supplements the water supply to the modern city of Siem Reap. Similarly, the Jayatataka (North Baray) – the last of the great reservoirs to be constructed in the twelfth century – was re-flooded recently by the Authority for the Protection and Management of Angkor and the Region of Siem Reap (APSARA National Authority), providing five million cubic meters of water for local communities and to recharge the severely depleted groundwater aquifer. In total, the rehabilitated water management network can store 65 million cubic meters of water, with plans to increase the storage to more than 100 million cubic meters (Peou, 2013). Once again, Angkor’s water management network is being used to secure livelihoods and support development as it did more than 600 years ago for one of the most extraordinary cities on Earth.

- field system (Dillehay et al. 1997). Upon excavation, two additional, earlier canal profiles lay bedded below the topmost canal profile. Apparently the earliest, bottommost canal was covered by a soil deposition episode requiring construction of a higher level canal; this canal was covered by a later deposition event and the uppermost canal built. Starting from the deepest canal, each successive higher canal had a shallower slope built over the depositional layer covering the previous canal. The cross-sectional area of successive canal profiles increased from the bottommost to the highest level canal. In essence, the ancients discovered a basic tenet of fluid mechanics: to maintain the same flow rate for all canal phases, the canal cross-sectional area must increase as the slope decreases. From these early origins, the archaeological record demonstrates continued progress in water management and hydraulic technology over millennia to meet the demands of large populations requiring predictable food supplies.
- Ancient Peruvian civilizations exhibited a wide variety of agricultural systems compatible with different ecological conditions found in coastal and highland settings. Peruvian north coast societies farmed alluvial river valleys using coastal rivers to supply water to canal networks supplying field systems. In south coast areas where rivers were deeply downcut from tectonic uplift and unable to support canal irrigation, underground galleries cut deep into the groundwater aquifer conducted water to distal surface field systems. In contrast to coastal irrigation practices, Andean highland agriculture depended on mountainside terraces supplied by rainfall and valley bottomland areas supplied by rainfall runoff streams originating from mountainous watershed regions.

Water Management in Ancient Peru

Charles R. Ortloff
CFD Consultants International, Los Gatos,
CA, USA

Water management in ancient Peru began in the north coast Zaña Valley (Fig. 1). Here a 2.5 km-long canal dating to 4705 BCE was sourced by the Rio Nancho and supplied water to a small

A characteristic of Andean coastal societies revealed from the archaeological record was their vulnerability to periodic El Niño flooding and drought (Moseley, 1987, 1997, 2008; Ortloff, 2009). Climate research (Abbott, et al. 1997; Binford, Kolata, & Brenner, 1997; Shimada, Schaff, Thompson, & Moseley-Thompson, 1991; Thompson et al., 1982, Thompson, Hastenrath, & Arnao, 1989; Weng et al., 2000) reveals sixth- and

Water Management in Ancient Peru, Fig. 1 Site map of Peru

tenth-century CE drought periods affecting survivability of major Andean societies (Ortloff & Moseley, 2008; Fig. 2). In other cases, flooding caused severe damage to canals and field systems through deposition/erosion events and geophysical landscape change that degraded agricultural and marine resource areas (Contreras, 2010; Moseley & Deeds, 1982; Ortloff, 2012). For extensive drought periods, the archaeological record indicates migration from homeland areas to areas with greater water/land resources (Dillehay, 2001). In other cases, intervalley canal construction projects were initiated to transfer water from adjacent, water-rich river valleys to resupply desiccated intravalley canal-supplied field systems (Ortloff, Moseley, & Feldman, 1983). Where reconstruction/repair solutions were not feasible for societies

whose water supply systems did not permit modification or innovative water management/transfer solutions, these societies disappear from the archaeological record (Fig. 2). In contrast to coastal societies, highland societies using terrace agriculture were able to transfer agriculture to higher terrace elevations where higher rainfall levels prevailed as drought initiated. For the Bolivian Tiwanaku society located on the Bolivian altiplano, raised-field agricultural systems dependent upon groundwater provided short-term drought defense (Ortloff & Kolata, 1993). In contrast, coastal irrigation relying on water from highland watershed areas sourcing coastal rivers was diminished by evaporation and ground absorption with only a small percentage available for irrigation agriculture. In northernmost Peruvian coastal valleys,

Water Management in Ancient Peru, Fig. 2 Agricultural strategies practiced by Andean societies subject to different ecological conditions: the variety

of categories shown are for natural and modified (artificial) landscapes for surface and subsurface (groundwater) water sources

societies constructed extensive intervalley canal networks to direct river water from adjacent valleys to intravalley farming areas (Kosok, 1985) to enhance agricultural production. As agricultural productivity for different societies was subject to frequent unstable weather/climate anomalies affecting water supplies, water management needed to be adaptable to changing environmental challenges to maintain production.

To quantify the development of water management and its relation to sustainability of different Andean societies, an equation governing

agricultural sustainability is presented consisting of terms relevant to agricultural productivity (water supply/management, agricultural system type, and vulnerability to flood/drought conditions, land area, fertility, population in balance with food supply), response to agricultural crises (technology innovation, food storage, labor supply), and intensity/duration of a climate change event. The equation sums contributions from these terms to yield a sustainability “score” characterizing different societies’ success or failure responding to climate crises given their

agrosystem's characteristics. While explanations involving environmental, sociopolitical, ideological, and cultural factors influence societal continuity and sustainability (Renfrew & Cooke, 1979; Bawden & Reycraft, 2000, 2009), the sustainability equation focuses on vulnerabilities of different agricultural systems used by different societies in different ecological zones to reveal causes for agricultural system failure (or success) under climate duress. In subsequent sections, all contributing sustainability (Q) equation components are discussed in detail as to their relevance to agricultural system sustainability/water management under climate change events and integrated into the subsequent Q equation section (**The Q Sustainability Equation**) to produce Fig. 4 results.

Runoff Ratio (R)

During drought, coastal farmland that normally supports an abundance of crop types supports a reduced number of types with low water demands and yields are reduced in response to lower water supplies. Sierra rangeland, in contrast, supports pastoralism and crops adapted to cold extremes based upon elevated rainfall amounts at higher altitudes. One reason for differences between coastal and highland agriculture under drought is related to soil properties that influence rainfall infiltration, runoff, and transport rates from highland rainfall sources. Highland soils retain water within their porous structure until saturation is reached; past this level, runoff occurs to supply coastal rivers sourcing valley irrigation systems. Channeled runoff is subject to evaporation and subsurface absorbance effects resulting in imbalances in the rainfall/runoff delivery rate from sierra to coastal areas. To illustrate effects of drought and the hydrological relationship between rainfall, soil properties, runoff and flow losses, a Moquegua Basin example is given.

The Moquegua Valley lies on the Pacific watershed west of Lake Titicaca. The valley river system is 139 km in length with headwaters reaching above 5,100 masl. Along the Moquegua

coast precipitation is negligible but increases gradually in the interior with altitude. However, the quantity of rainwater only exceeds saturated retention values in 19 % of the basin above 3,900 masl. Between 3,900 and 4,500 m, average rainfall is ~360 mm/year and about 260 mm of this amount is retained in saturated soil so that only 100 mm is available as runoff (ONERN, 1976). In this zone, a 10 %, or 36 mm, decline in rainfall to 324 mm decreases runoff by 36 % from 100 to 64 mm. For soil retention capabilities typical of this area, a 15 % decrease in rainfall results in a 54 % decrease in runoff. In the elevation zone between 4,500 and 4,900 masl, rainfall averages 480 mm/year and a 10 % or 15 % rainfall reduction results in runoff reductions of 21.8 % and 32.7 %, respectively. Comprising less than 3 % of the Moquegua Basin, precipitation above 4,900 masl is principally snow and ice, and the runoff contribution is unknown as the amount of moisture retained in glaciers and snowfields is unknown. For the upper river basin, rainfall declines of 10–15 % result in runoff reductions of 25–40 % or more. The asymmetric relationship between rainfall and runoff works in reverse: increased precipitation rapidly saturates soil and amplifies runoff. Other than during spring floods, the valley river does not normally carry surface flow at elevations below 1,200 masl and farming in the coastal section of the drainage depends on groundwater springs originating high in the river basin. The relationship between highland rainfall and coastal spring flow is asymmetric because subsurface water flows through aquifers of different porosity, permeability, and saturation values. Although these values are poorly known, coastal spring flow may have dropped by 80 % during the tenth- to eleventh-century CE drought (Ortloff, 1989, 2009). Coastal river hydrographs track availability of coastal irrigation water over time and variations exist between coastal valleys depending on soil geomorphology, topography, agricultural activity, and temperature/humidity history. Nonetheless, drought has a greater effect on coastal irrigation farming than on sierra rainfall farming. Even after the arrival of irrigation water to coastal field systems, approximately 85 % is

lost to evaporation from soils leaving only 15 % absorbed by plant roots. In dry periods, rain at high altitudes may sustain limited highland agriculture but coastal agriculture derived from runoff into rivers from the same watershed will experience a severe irrigation water deficit.

To quantify these effects, a Runoff Ratio (R) is defined as the average rainfall runoff rate from a watershed area divided by the average rainfall delivery rate to the same area. Coastal societies dependent upon irrigation from highland runoff sources are characterized by $R < 1$ in normal rainfall periods and $R \ll 1$ under drought conditions. Societies dependent upon groundwater-based agriculture experience $R < 1$ in normal rainfall periods due to limited rainfall infiltration to groundwater and $R \approx 0$ under extended drought conditions. Highland terrace systems dependent upon rainfall have $R \approx 1$ in normal rainfall periods and $R \ll 1$ under drought conditions. Here drought is not necessarily total absence of rainfall but rather a decrease in average seasonal levels over an extended time period.

Vulnerability Index (V)

Another component influencing agricultural sustainability/water management is the design and function of field systems given their water supply systems. Different sites throughout Peru employed different agricultural systems (Fig. 2) tailored to local ecological conditions. Each system type is assigned an integer V value (Fig. 3) related to its ability to maintain productivity at different water supply levels. The relative integer values rank the survivability of different systems relative to each other under water deficit conditions. Highly vulnerable agrosystems rely on a continuous supply of water from seasonal rainfall runoff; when long-term drought occurs, these systems fail as $R \ll 1$. Raised-field agriculture (Fig. 3, Index 1), widely practiced by the 300 BCE–CE 1100 Tiwanaku society (Kolata, 1993; Kolata & Ortloff, 1989; Moseley, 1992) on altiplano areas bounding the southern periphery of Lake Titicaca, consisted of agricultural soil mounds constructed from excavated troughs.

Troughs were dug below groundwater level and were relatively invulnerable to short-term drought as groundwater recharge flow from infiltrated rain deposited into distant watershed areas continually sustains the groundwater level in troughs. Raised fields were relatively invulnerable to excessive rainfall because elaborate field drainage canals shunted excess water directly into Lake Titicaca limiting groundwater infiltration. Because rainfall infiltration and Lake Titicaca height vary with seasonal and longer-term rainfall/runoff fluctuations, the groundwater profile necessary to maintain the swale water height and the phreatic zone within raised-field mounds to support different crop types is altered. Thus, shifting of agricultural zones toward available high groundwater areas distant from Lake Titicaca margins sustained limited agriculture during drought and provided limited agricultural sustainability. The next least-vulnerable agricultural systems to drought are sunken gardens dug to the phreatic groundwater boundary to support agriculture (Index 2). Here the slow decline of groundwater level yields relative invulnerability to short-term drought. The next level of vulnerability (Index 3) is represented by agricultural terraces widely used by highland societies. Terraces supplied by normal rainfall levels provide a highly productive agricultural system, but when rainfall diminishes, these systems become marginal for production unless supplied by snow melt and/or spring-channeled water. Next in increased vulnerability (Index 4) is canal irrigation practiced by Peruvian north and south coast societies. These systems are productive when highland rainfall exceeds saturation conditions ($R \approx 1$) but vulnerable due to the asymmetry between highland rainfall and runoff to coastal valleys. Generally, long canals are more vulnerable (Index 5) than short canals due to greater seepage/evaporation losses. Yet more vulnerable systems (Index 6) are coastal seeps that supply agriculture in the Ilo area of the Moquegua Valley (Fig. 1) and rely on groundwater seepage to coastal areas over long underground distances. A variant of these systems found in the Casma Valley (Moore, 1988, 2000, Figs. 1 and 2) represent temporary, high productivity agriculture

Water Management in Ancient Peru, Fig. 3 Vulnerability Index classification values; different agricultural systems exhibit different vulnerabilities to

drought/flood conditions depending on defensive designs that incorporate memory of prior climate/weather events

derived from infiltrated El Niño rains amplifying the valley water table profile. Survival of the more vulnerable agrosystems is questionable below a critical water supply level (DD, Fig. 3) with system extinction inevitable whenever reconfiguration to a lower vulnerability system is impossible. A Vulnerability Index ($1-V$) defined in Fig. 3 is such that the largest values of the index denote the least-vulnerable agrosystems.

Technology

Agrosystem sustainability subject to weather/climate variations depends on the ability to modify/incorporate a defensive water management technology T in time t , denoted as (dT/dt) , faster than the creation/evolution rate of a climate-related

disaster (dD/dt) in the form of floods and/or extended duration drought. For $0 \leq dT/dt \leq 1$, $dT/dt = 0$ means no timely water management/engineering modifications available/possible to defend against severe climate challenges; $dT/dt = 1$ denotes engineering/labor/management solutions available to maintain/sustain productivity during climate challenges. To quantify the definition of climate-related disaster between limits $0.5 \leq dD/dt \leq 5$, reference is made to the duration and severity of drought/flood periods indicated by ice core, limnological and paleobiotic data (Abbott et al. 1997; Contreras, 2010; Tapia et al., 2000; Thompson et al. 1982, 1989). Societies utilizing a low-vulnerability agricultural system dependent upon groundwater exhibit a slow response to drought for which dD/dt is low (~ 0.5); societies dependent upon high- vulnerability canal

irrigation experience rapid decline in water supplies from low runoff during drought for which dD/dt is high (~ 5). For flood events, dT/dD is low due to the rapid destructive onset of flood-water on canal irrigation systems that lack flood defenses. While some flood defense systems have been noted in the Intervalley Canal and Jequetepeque Valley canal systems (Ortloff, 2009), research in this field is in a preliminary stage.

The Q Sustainability Equation

In literature related to the collapse of civilizations (Diamond, 2004; Renfrew & Cooke, 1979; Scarborough, 2006), causative criteria link damage from climate change effects on agriculture as one of several factors influencing societal transformation. The basic premise is that if agriculture fails, then societal transformation is inevitable. Factors affecting agricultural sustainability for systems of different vulnerability classes include use of food storage structures (S), water engineering to counter an agricultural production decline (dT/dt), and a labor force as a fraction of the total population P' to implement defensive strategies. Other factors include field system yield per unit area (Y), field area under production (A), and the available water supply (R). The time-dependent magnitude of a developing climate threat (dD/dt) in relation to the rate of water engineering defense against developing threats (dT/dt) is a further element in the trend equation that influences agricultural sustainability. The influence of individual terms is given by numerical values to denote their presence, use intensity, and application. The sum (Q) of numerical values from individual components permits a “score” useful to compare different societies’ success or failure dealing with climate-related stress. Quantities (Q , R , S , V , A , Y , P' , dT/dt , dD/dt) are number values normalized to the maximum reference state for each variable. A large value of Q over time connotes agricultural sustainability, while a small value denotes the opposite. In the trend equation, values specified for the Vulnerability Index are shown in Fig. 3; S is given a numerical

value depending upon its presence or absence; P' reflects the degree to which population is balanced with the available food supply and the derivative terms indicate the duration and magnitude of drought events and defensive engineering technologies available to maintain agricultural sustainability. The Q equation applies for a closed system (food supply from near vicinity areas of a capital city/satellite center with no imports from remote areas) and is given as

$$Q = S + YAR + (1 - V) + P'(2 - P')(dT/dt)/(dD/dt)$$

Here R is the Runoff Ratio ($0 \leq R \leq 1$), S the agricultural storage capacity ($0 \leq S \leq 1$) normalized to S_{mx} where $S = 0$ represents no crop storage, and $S = 1$ represents storage of all non-consumed crops. Intermediate S values indicate limited food storage facilities for defense against short-term crop failures. $(1 - V)$ is the agricultural Vulnerability Index ($0 \leq V \leq 1$). YAR represents crop yield per unit area (Y) times the total field area (A) in production times the available area water supply; parameters are normalized to their maximum values so that $0 \leq YAR \leq 1$. The lower limit indicates poor crop yield over a small land area with limited water supplies, while the unity limit indicates high crop productivity over the largest available agricultural area sustained by irrigation. $P' = P/P_{mx}$ is the population where P_{mx} is the maximum possible population sustainable by the agrosystem. When $P' = 1$, then $P'(2 - P') = 1$ at the maximum population level sustained by the food supply (or, equivalently, $\partial Q/\partial P' = 0$ at $P' = 1$). If $P' \rightarrow 0$, then $P'(2 - P') \rightarrow 0$, resulting in a small population as may occur after a natural or man-made disaster. Thus, $0 \leq P'(2 - P') \leq 1$ is the range of population variation from balance with the food supply ($P' \approx 1$) to out-of-balance extremes that limit the labor force as a fraction of P' necessary to implement labor-intensive farming or construction tasks. The lower limit may result from out-migration, famine, warfare, or other population decline/dispersal situations resulting from climate/political/economic instabilities, while the upper limit represents a stable

food supply/population balance. Intermediate values result from population size adjustments to declining food supply from a variety of destructive weather/climate effects and signal-insufficient labor to implement defensive measures for a sufficient $dT/dt \rightarrow 1$ response. The engineering/technology term $0 \leq dT/dt \leq 1$ represents the time rate of technology (T) change to counter destructive weather/climate change effects on agricultural production (excessive rainfall, drought, climate-induced geophysical landscape changes); $dT/dt = 1$ represents engineering technology sufficient to successfully respond to agricultural duress with remediation repair/modification efforts. The dD/dt term represents the rate of disaster-producing effects; for $0.5 \leq dD/dt \leq 5$, large values occur for rapidly evolving disasters (e.g., El Niño flood events) and small for slowly evolving weather/climate variations that pose gradually increasing threats to agricultural production. When $(dT/dt)/(dD/dt) = dT/dD \rightarrow 2$, engineering technology to defend against slow decreases in water supply exceeds the rate of disaster evolution leading to positive contribution to agricultural sustainability. If a flood event occurs beyond any defense counter to provide field system protection, then $dT/dD \rightarrow 0$ indicating little or no contribution to agricultural sustainability. If a weather-/climate-related disaster evolves at the same rate as defensive response technology, then dT/dD is a positive number with a contribution to sustainability. If $P' < 1$, the labor to make rapid dT/dt corrections is not available and Q decreases. If $P' \rightarrow 1$ in the presence of a declining water supply, then agricultural resources are inadequate to feed a large workforce over time to ensure rapid dT/dt changes. Thus, only population balanced with agricultural supply promotes large Q values. From the Q equation, sustainability is enhanced when the runoff ratio/water supply (R), land area (A) in cultivation, and crop storage (S) are high, a stable population is balanced with agricultural output ($P' = 1$), system $(1-V)$ vulnerability is low, the engineering innovation rate dT/dt exceeds the weather/climate-induced disaster evolution rate dD/dt , and soil productivity (Y)/unit water input is high. High Q values over time indicate a society with foresight to maintain sustainable agriculture

despite weather/climate variations; low Q indicates gaps in the perception of climate threats and inadequate disaster defenses resulting in marginal agricultural system performance. For extreme, long-lasting drought, Q ultimately drifts to smaller values in time indicating that sustainability is no longer possible.

Numerical Values for the Q Equation

To illustrate Fig. 4 Q values for drought originating in the tenth to eleventh centuries for the Chimu Moche Valley presence, $S = 0.5$ indicating comestibles storage within Chan Chan but few other compounds devoted to food storage. $(1-V)$ is ~ 0.5 indicating dependence upon runoff-based, short intravalley canal systems. YAR is composed by $Y = 1$ from fertile alluvial valley soils for large agricultural areas ($A = 1$), but $R = 0.5$ indicating decreasing tenth-century highland runoff to Chimu field systems. $P' = 1$ indicating a population previously balanced with food resources before drought onset. dT/dt is close to unity to improvise technological changes to combat drought but $dD/dt \approx 2$ with higher values immanent as drought intensified over time. Summing up the contributions from individual components, $Q \approx 0.5 + 1 \cdot 1 \cdot 0.5 + 0.5 + 1 \cdot (1/2) = 2$; this value is represented by point A in Fig. 4 and presages late LIP abandonment of Moche Valley agrosystems as drought intensified. As a further example, Tiwanaku society experienced tenth- to eleventh-century drought; here $S = 0.4$ from urban circular structures used as food storage facilities with $YAR = 0.8 \cdot 0.8 \cdot 0.4 = 0.24$ representative of declining yields from declining areas as drought progressed. As raised fields are dependent upon groundwater/spring water, $(1-V) \approx 0.5$ indicating increased vulnerability as drought progressed. $P' = 0.95$ reflecting a trend away from population levels balanced with food supplies as tenth- to eleventh-century drought continues. As immediate consequences of drought on groundwater-dependent raised-field systems was gradual, $dD/dt = 0.5$; this value increases steadily as drought intensified over time. Labor to alter

Water Management in Ancient Peru,

Fig. 4 Sustainability Q values versus time for different Andean societies

vast raised-field areas to follow down the declining water table was not available implying $dT/dt = 0.6$. Summing up individual contribution components,

$Q \approx 0.4 + 0.24 + 1 + 0.95 \cdot (0.6/0.5) = 2.8$ and is represented by point **B** in Fig. 4 at tenth-century drought initiation. Later times experience severe Y, R, and urban P' decreases leading to abandonment of Tiwanaku city. Data from early phases of other major societies in periods of adequate rainfall and terminal phase drought are used in Fig. 4.

Historical Climate Variation and Agricultural Sustainability of Andean Societies

Intermediate and Horizon periods characterize Andean historical patterns. The Early Intermediate Period (EIP, 100 BCE–700 CE) is characterized by north coast Moche architectural/agricultural complexes, central coast Lima societies, and south coast Paracas and early Nazca societies. EIP Moche settlements south of the Jequetepeque Valley and south coast Nazca settlements had minimum Q values in the sixth- to seventh-century CE coincident with a drought episode (Shimada, 1994a, 1994b; Shimada et al., 1991; Thompson et al., 1982, 1989) and

relied on runoff water channeled into coastal river valley irrigation systems; the Nazca relied on groundwater-based, subterranean gallery water supplies. Drought reduced agricultural sustainability for Index 4 and 5 systems characteristic of north and south coasts where low R prevailed. Late EIP transfer of Moche traditions to northern coastal valleys and integration with local Gallinazo societies led to new city centers (Bawden, 1999, 2010; Bawden & Reycraft, 2009; Shimada, 1994b) with amplified land and water resources for agriculture. Seventh-century CE drought influenced collapse of Lambayeque Valley Sicán society with abandonment of Batán Grande. Later construction of Tucumé resurrected Sicán society only to fall to Chimu expansion in the fourteenth century CE. During the Middle Horizon (MH, 700–1000 CE), Tiwanaku and Wari societies dominated the southern/central Andean highlands through political, economic, military, and religious influences. Wari settlements in the Ayacucho area were supplemented by dispersed administrative centers at Pikillaqta, Cajamarquilla, Viracochapampa, Cerro Baúl, Huanuco Pampa, Jincamocco, Chuquibamba, and Wari-Wilka. The Late Intermediate Period (LIP, 1000–1490 CE) was characterized by Chimu north coast occupation from the Chancay to Lambayeque coastal valleys (Mackey, 2009) with administrative centers (Farfán,

Manchan, Purgatorio, Túcume) and ceremonial centers (Pacatnamú, Chotuna) administered from the capital city of Chan Chan. Centrally administered, multi-valley agricultural complexes directed from satellite administrative centers sharing common political/social/religious practices characterized LIP times. Inka military conquest and dominance of highland and coastal societies characterized the Late Horizon (LH, 1490–1532 CE). The climate change history reflected in the Quelccaya/Huascarán ice cores (Thompson et al., 1982, 1989), Lake Titicaca, and Cuzco area sediment cores (Abbott et al., 1997; Binford et al., 1997) indicate drought episodes (570–610 and 650–730 CE) in the late EIP influencing decline of coastal Moche and Nazca polities. Drought-induced low Runoff Ratio R combined with high-vulnerability irrigation systems resulted in low dT/dD as water management strategies/engineering innovation could not overcome long-term drought effects.

In early LIP times the Chimú brought water management to a high level through advanced hydraulic technologies (Ortloff, 2009) that permitted the development of intravalley canal networks (Fig. 2). As drought progressed in late LIP centuries, a limited degree of Moche Valley irrigation restoration occurred through combined use of the Chicama-Moche Intervalley Canal and Chimú strategy involving transfer of agriculture to northern valleys away from their Moche Valley heartland through conquest of the Lambayeque Valley Sicán ~1375 CE that provided large land areas and high flow rate rivers.

The Tiwanaku achieved high sustainability until the long-term tenth- to eleventh-century drought lowered the water table beyond levels to support agriculture. Sustained drought reduced annual rainfall levels by 5–10 % from previous norms depressing water table height and agricultural yield. Relocation of agricultural zones to distant high water table areas and employment of *cochas* marginally extended sustainability as drought progressed resulting in population resettlement in small groups away from city precincts (Janusek, 2004). Wari penetration into the Moquegua Valley was enhanced by a short period of above-average precipitation in early MH

times, but toward late MH, diminishing rainfall levels undermined agrosystem productivity as multi-century drought set in after ~1100 CE (Abbott et al., 1997; Baker et al., 2001; Thompson et al., 1982). Wari sites in northern sierra locations were abandoned in this time period. While Tiwanaku raised fields had capability for agricultural area shifts, the option to lower all 80,000 km² of raised-field troughs to follow down the retreating water table would require vast labor input, while food supplies continually declined. Thus, no long-term drought recovery was possible for the Tiwanaku society past 1100 CE. In contrast, multi-valley Chimú canal networks monitored through dispersed, state-controlled administrative centers utilized advanced water management technologies and large labor resources permitting installation/expansion of irrigation systems supplied by larger flow rate rivers in conquered and settled far north coast areas. Although highland terrace agriculture countered drought by elevating farming zones to take advantage of higher rainfall levels, yields (Y) decreased due to poor soils, cold, and decreased farming area (A). The MH Wari expansion into northern coastal/sierra territories provided new territories and colonies with less vulnerable agrosystems than their heartland terrace systems. While details of Wari expansion are fragmentary, little is seen of Wari sites past twelfth century CE indicating decline of coastal and highland administrative centers (Fig. 4).

Expansion of Moche, Tiwanaku, Wari, and Chimú societies away from their heartland capitals was their strategy to gain additional resources in territories with less vulnerable agrosystems (Murra, 1985). The water supply advantage to highland systems was manifest in the LH to the advantage of the Inka as rainfall levels restored to earlier norms. The Inka policy of population relocation to revitalize lowland agricultural centers in different ecological zones (D'Altroy, 2003) initiated the end of conquered LIP societies. The Inka were beneficiaries of increased LH rainfall as successive rulers expanded conquered territories and resettlement of conquered peoples to industrialize agriculture to high productivity levels. With Inka conquest and incorporation of Chimú

territories in the late fourteenth century CE, the Chimu disappear from the archaeological record as their cultural symbols, practices, cities, and settlements were subsumed by Inka overlords.

Figure 4 shows Q histories for major Andean societies and illustrates that climate change appears to be a significant factor influencing Andean historical patterns. While societal socio-political events influence transition scenarios, once the agricultural base collapses, the foundational underpinnings underwriting societal continuity are altered.

Conclusions

Without sustainable agriculture and water management practices that can survive weather/climate excursions beyond norms on which agricultural system designs were originally made, destabilizing conditions challenge societal continuity. As an example, LIP Chimu water management proceeds through intravalley canal rebuilding/modification/extension programs and flood/drought defensive measures (Ortloff, 2009, pp.199–204) that increase cultivated land areas and productivity commensurate with increasing population demands. They show, under tenth- to eleventh-century climate change duress, intervalley mega-canal building projects and conquest of northern valleys as the solution to sustain and grow agriculture. For the MH Tiwanaku, no major modifications were available to continue raised-field agriculture as groundwater levels declined and limited raised-field agriculture leading to abandonment of the capital city in the tenth to eleventh century. MH Wari society likewise declined due to drought in the same time period as their terrace agricultural systems failed under decreased rainfall amounts. Figure 4 indicates results for other major Andean societies in response to sixth- and tenth-century droughts leading to their continuance or disappearance from the archaeological record depending upon the flexibility and adaptability of their agrosystem designs to allow water management/engineering response technologies under decreasing water supply. Thus, water

management survival strategies continually developed to match climate challenges over time for Andean societies, and the success of these strategies decided either their survival or collapse as the archaeological record indicates.

Water Procurement in the Prehistoric Caribbean

Peter L. Drewett

When Ceramic Age peoples arrived in the Caribbean, water was readily available on some volcanic islands like Dominica but virtually absent on most of the coral islands like Barbados. Initially this would have been a major constraint to settlement and survival. In years of regular rainfall, rainwater could be collected from rock pools, caught in foliage of plants and collected in pottery vessels or even upturned conch shells. When the rains failed, however, drought would have led to serious problems on islands without the ability to maintain surface water supplies in the form of rivers

and streams. On at least three islands in the southern Caribbean, Barbados, Mustique and Carriacou, Amerindians developed a specific alternative way of guaranteeing a water supply. It may be assumed that the technique was used on other islands although archaeological evidence has not yet been located.

On coral rock islands (Machel, 1999), where the bedrock is highly permeable, salt seawater may infiltrate under all of the island or at least around the coastal fringe. Rainwater falling onto the island will seep down until it reaches denser salt water. It will then flow towards the sea on this denser water. At the head of beaches it will be quite shallow before it mixes with seawater (Schultz, 1995). Somehow Amerindians recognised this source of sub-surface fresh water and tapped into it. Although similar to sinking wells elsewhere in the world, the process of tapping into this water required great skill; otherwise salt and fresh water would be mixed and the water source spoiled.

Excavations at the Amerindian settlement at Heywoods (Port St Charles) on the west coast of Barbados revealed two methods used to tap into this shallow supply of fresh water (Drewett, 2000). The main Ceramic Age settlement at Heywoods was occupied from about AD 600 to AD 1200 (Late Saladoid – Troumassoid). Several round houses and burial areas have been excavated together with wood- and pot-lined water holes (Drewett, 2000).

Two wood-lined water holes were excavated. These consisted of wood planking some 1 m in length sunk into the soft sand and held in place by large coral rocks. Both were roughly square in shape (Fig. 1).

The wood used was false mastic (*Mastichodendron* sp.) and *lignum vitae* (*Guaiaecum* sp.). One was dated to ca. AD 780–1020 (B-147314) and the other to ca. AD 790–1030 (B-147313). In both wells calabash (*Crescentia cujete*) remains were recovered suggesting these were used to scoop up the fresh water (Fig. 2).

More common, and possibly more successful, were the pot-lined water holes. A shallow hole was dug into the underlying wet sand and a large

cooking/storage pot was sunk into the wet sand. These pots had been pre-prepared with their bases carefully removed (Fig. 3).

The pot was carefully pressed into the wet sand while more sand was scooped out of the interior. Additional pots were then stacked on top, acting as a cofferdam to stop wet sand slumping back in. The pots were held in place with coral rock boulders and/or wooded wedges. After a couple of hours any sediment in the water

Water Procurement in the Prehistoric Caribbean, Fig. 3 Large cooking/storage pot with base removed found in pot-lined water hole at Heywoods, Barbados. ca. AD 1000–1200 (Source by author, photo by Abel Drewett)

would settle with the pressure of the underlying water pushing the fresh water up into the pot-lined hole (Figs. 4 and 5).

It is uncertain whether these pot-lined water holes were left open or had a removable cover. None were found covered although several had large sherds of pottery in the water holes, which could have been used as lids. Flat cassava griddles found elsewhere on the site would have also made suitable lids, as would organic materials like large leaves or planks of wood. A major problem was probably local soiling of the water by domestic rubbish or even human burials, which were also within the domestic area. This might explain why holes had to be regularly

Water Procurement in the Prehistoric Caribbean, Fig. 5 Pot-lined water hole at Heywoods, Barbados, ca. AD 1000–1200. Section view (Source by author, photo by Abel Drewett)

replaced. Twenty three were systematically excavated during the main phase of salvage excavations at Heywoods during 1998/1999, but many more were noted during building work for the Port St Charles marina constructed on the site.

Some of the pot-lined water holes had a highly decorated pot rest resting on the top of the stack. These are like ceramic collars in which large unstable pots were set to make them stable on uneven ground. One found was 32 cm in diameter and 17 cm high. It was red-slipped with white on red paint and grooved decoration in a concave-ended rectangle and vertical line pattern. This was among the finest pottery found on the site, so it would suggest great importance of the mouth of the hole. Tapping into this underlying source of water may have involved great perceived risk involving careful ritual, for Amerindians believed that a river of the dead ran under their houses and settlements. Ritual specialists were no doubt involved in the placing and digging of these pot-lined water holes and perhaps hallucinogenic drugs, like cohoba, were taken prior to digging rituals (Drewett, 2002).

How widespread the use of pot-lined wells was in the prehistoric Caribbean remains uncertain particularly because of limited archaeological excavation in the southern Caribbean. To date they have certainly been recorded on three

sites on Barbados: Heywoods, Spring Garden and Maxwell. They have also been recorded on Mustique and Carriacou. Many further examples may have been lost by coastal erosion or await discovery.

Water Systems in Bronze and Iron Age Israel

Avraham Lynch¹ and Helaine Selin²

¹Bar-Ilan University, Ramat-Gan, Israel

²Hampshire College, Amherst, MA, USA

The Near East is located on the edge of the desert. Part of the region is arid/semiarid, and as droughts are a frequent phenomenon, water is a scarce resource even in the Mediterranean climate zone. Water was therefore an important factor determining the situation of settlements in antiquity. Initially, many settlements were located near water sources, mainly springs (rivers are a rare phenomenon in Israel). However, since security was also a major consideration, larger settlements gradually tended to be situated on top of hills. In this conflict of interests, security had, in most cases, the upper hand, and alternative means of obtaining drinking water had to be secured.

Wells

A well is an artificial shaft sunk into the ground all the way to the water table. One of the earliest known wells was uncovered at the submerged Neolithic village of “Atlit Yam.” Later wells are known from Beersheba, Lachish, and Tel Zeror, and it seems as if the practice became widespread from the Iron Age onward (and mainly from the Classical periods). Notably, however, wells are typical of lower regions and plains. It is more difficult to dig wells in mountainous areas because of both the depth of the water table and the hardness of the rocks. Wells were, therefore, only a partial solution, and in most cases, people used different methods (see below).

Cisterns

Cisterns were cut out of rock in order to collect and store rainwater. The first known cisterns were apparently dug into the soft limestone of the coastal plain in the late Chalcolithic or Early Bronze Age at Mesar. The earliest cisterns were not plastered, but due to the softness of the stone could still hold the water. The first plastered cisterns were discovered in several Middle Bronze Age sites (e.g., Hazor and Gezer) (see section “[Extra 1: The Open Cisterns of the Negev in the Tenth Century BCE](#)”). Their use, however, was still sporadic. Plastered cisterns became widespread only during Iron Age I and mainly in Iron Age II. The use of cisterns became even more widespread in later periods. While cisterns became common and at times dozens of cisterns were unearthed in a single site, it appears that they were still dug at the family level. Communities, let alone cities/states, had to develop a better solution to the danger posed by the scarcity of water.

Large-Scale Waterworks

Large settlements, if not located on a large spring or a river, needed a guaranteed water source for the summer, and all the more so for periods of

siege. After all, the fate of a conquered city in the ancient Near East was horrific, and any effort was done to secure the city and to enable it to withstand siege.

The earliest large-scale waterworks, evidently beyond the scope of the household, are dated to the Early Bronze Age – the time period when the first cities emerged in the southern Levant. These early water systems are basically large pools, usually located in the lowest part of the settlements, into which rainwater was collected. Such systems were found at “Arad,” Ai, and probably also at Tel Qashish. “Arad, located on the edge of the desert, is a unique example. The city was built not on top of a hill, but rather on a basin, probably in order to ease the collection of water. A slightly different type of water system was located outside the city of Jawa, in Transjordan. Here, dams were built on a dry wadi, absorbing floods, and securing water for the dry season. Such large-scale works were able to support a large population.

Still, in the climatic conditions of the land of Israel, in which droughts are frequent and evaporation is high, rains and pools cannot be regarded as a secure source of water. In cases of failing rain, people would have to go to the nearest spring (usually just below the city). In times of siege, however, which began to become a major consideration as time progressed, such an enterprise was not feasible. Cities had to rely on a more permanent and secure source of water. They developed more sophisticated methods to guarantee access to permanent sources of water, i.e., to springs (which were usually located in the valleys below the cities).

Waterworks technology seems to have advanced substantially in the first half of the second millennium BCE. The notable water system of this period (Middle Bronze Age) is that of Jerusalem (see section “[Extra 2: Jerusalem’s Water Systems During the Iron Age](#)”). Here, an attempt was made not only to collect rainwater but also to secure access to the water of the nearest spring – the Gihon – which was located below the city at the Kidron Valley. From within the city, a large tunnel was dug in the hard limestone. The tunnel went outside the city wall until

it reached a fortified pool that was built on the spring and stored its water. An additional water system which is probably dated to this period was exposed at Gezer. Here, a tunnel was dug within the city's confines, reaching the water table (similar to type 3, below, but much earlier).

The real "breakthrough" in water systems, however, was accomplished during the Iron Age and mainly during Iron Age II. A relatively large number of Iron Age water systems were unearthed over the years, and these can be divided into the following types:

1. Covered stairways (galleries). This is the simplest form of Iron Age waterwork. A shallow tunnel was dug on the tell's slope, from beneath the city wall, all the way down to the spring. (A tell is an artificial mound formed by the accumulated remains of ancient settlements.) The tunnel was then covered. Thus, in times of siege, city inhabitants could sneak from the city to the spring through the covered stairway without being seen by the enemy. Such systems were discovered in Megiddo and Tell es-Saiyidyeh. Obviously, these systems had their limitations. The spring was known to the enemy, and the gallery could easily be discovered. Once discovered, it could not have been used anymore.
- 2a. Tunnels. Many Iron Age water systems were dug under the ground, from within the city to the spring. Initially, a large shaft was dug through the earlier layers of the tell. Since these were pretty loose, the shaft was supported by massive retainer walls that prevented their collapse. After reaching bedrock, a smaller tunnel was dug in the rock, at an angle that lowered it toward the spring. Such systems were discovered, for example, in Gibeon and Megiddo (early phase of the tunnel).
- 2b. A modification of this type of water system is also known. In some cases, a tunnel brought the water from the spring toward the bottom of the shaft (i.e., toward the city). Such systems are known, for example, at Megiddo (a later phase), the Warren Shaft system in Jerusalem (see note: Jerusalem water system during the Iron Age) is a variation of this type.
3. "Tunnels" dug to the water table. This type is very similar in its form to the previous one. A wide vertical shaft was dug through the tell's layers to bedrock, and this was followed by a narrow diagonal tunnel that was dug in the rock. This diagonal tunnel, however, did not reach the spring; it descended until it reached the water table (in a sense, this waterwork was like a complex well). While very similar in form to type b, this is simply a large and complex well. Such systems were not only concealed from the enemy, but were also completely secured. Some were discovered, for example, at Hazor and Gibeon (the pool).
4. The last type of large-scale Iron Age waterworks is that of large underground reservoirs, dug into bedrock (inside the cities). Rainwater was collected through an extensive system of plastered tunnels (e.g., at Beth Shemesh) or from floodwaters in nearby wadies (Beersheba). (A wadi is a valley, ravine, or channel that is dry except in the rainy season.) Smaller reservoirs are also known in this period, e.g., in the fort at "Arad." While not as reliable as permanent water sources, it appears as if such large reservoirs could absorb enough water underground to overcome the limitations discussed above (regarding the dependence on rainwater).

The galleries (type 1) were the simplest type, and indeed, they were used earlier in the Iron Age. It appears as if type 2 was developed to overcome the limitation of the galleries. Type 3 was seemingly the most advanced system.

We do not know if these systems were developed on the basis of the knowledge that there was a water table “down there” (the people of the time had to have had this knowledge, as they were familiar with wells) or whether hewers of a type 2 system accidentally reached the water table, and this discovery gave rise to the development of this type (structurally, type 3 is very similar to type 2). This reconstruction is of course speculative, and we need more detailed chronological information in order to confirm or refute it. We also need to remember that some complex water systems were already constructed in the Bronze Age, as mentioned above.

Various water systems are also mentioned briefly in the period’s written sources, e.g., the Bible (e.g., II Kings 20: 20; Isaiah 22: 9–11; II Chr. 32: 30), and ancient inscriptions (e.g., the Mesha inscription).

The most sophisticated Iron Age water system is Hezekiah’s tunnel, which was dug in Jerusalem during the late eighth century BCE. A 533 m long underground tunnel brought the water from the Gihon spring to a lower point that was located in the other side of the city, in order to collect the water in a pool in a secure place.

In later periods, and especially from the Hasmonean and Roman period onward, larger water systems, e.g., 10 km of aqueducts, were built, but this is beyond the scope of this entry.

Extra 1: The Open Cisterns of the Negev in the Tenth Century BCE

During the tenth century BCE, the period of the biblical United Monarchy, dozens of settlements were built in the Negev desert of southern Israel. The exact nature of these sites is debated: some view them as royal forts and others believe that only the initiative was royal, while some consider that the entire phenomenon resulted from the settlement of the desert’s nomads. Notably, these sites were located away from the few springs that exist in the Negev, and their main source of water was large open cisterns that were discovered at practically every site. These large cisterns were probably covered with skins in

order to minimize evaporation. It is also likely that when the rains failed, the inhabitants of many of the sites could go back to the springs, located several kilometers away, and bring drinking water from them.

Extra 2: Jerusalem’s Water Systems During the Iron Age

The Gihon spring of Jerusalem is one of the major springs in the central hill country. It is likely that it was one of the causes for the establishment of the city on the low hill, later known as the City of David. The inhabitants of the city used the spring from earliest times. The most ancient water systems are two tunnels, probably dated to the Early or Middle Bronze Age. During the Middle Bronze Age, an impressive water system was dug in Jerusalem (above in the text). It is during the Iron Age, however, that the most famous waterworks were constructed. As many issues are still debated, the following is only a brief summary that is intended to give a succinct overview, and it cannot deal with all the debated details. The earlier Iron Age system, known as the Warren Shaft (after Captain C. Warren who rediscovered it in the nineteenth century), enabled free access to water through a system of underground tunnels and a shaft. In the past, many scholars believed that it is through this shaft that David conquered Jerusalem (II Samuel 5: 6–9). It appears, however, that this system was constructed only in the eighth century BCE. At this time, improvements were made in the existing system of tunnels (that were cut in the Middle Bronze Age). The works included lowering the bottom of an existing tunnel that led from within the city wall, outward (henceforth, the upper tunnel), thus, exposing a natural karstic shaft that was probably not known before (although some dispute this). Once the shaft was discovered, and its significance was apparently observed, previous works ceased, and it became the central part of a new system. A lower tunnel, connecting the spring and the bottom of the shaft, was dug, enabling the water to flow from the former to the latter. Thus, people could walk in

the upper tunnel, from within the city walls to the top of the shaft, and draw water. The level of the water at the bottom of the shaft was increased through the use of dams, making water drawing easier. Notably, this system was not very convenient and was probably intended to be used only at times of siege. The Warren Shaft system, however, was not in use for long, and it went out of use in the late eighth century BCE, when Hezekiah's tunnel was constructed. Hezekiah's tunnel involved the digging of an underground tunnel that led from the spring to a pool at the other side of the City of David ridge, within the city walls. Hence, all the water from the spring was secured. The last stage of the enterprise involved the meeting of two groups of hewers who worked from both sides of the tunnel simultaneously; this is commemorated in the famous Siloam inscription. (The inscription was discovered in 1880 by a boy who was bathing in the waters of the Gihon Spring and was studied by Conrad Schick, one of the first explorers of Jerusalem. Engraved in the rock, the inscription describes the meeting of the two groups of hewers who had begun digging from opposite ends of the tunnel. "The tunneling was completed. . . While the hewers wielded the ax, each man toward his fellow. . . there was heard a man's voice calling to his fellow. . . the hewers hacked each toward the other, ax against ax, and the water flowed from the spring to the pool, a distance of 1,200 cubits. . . ." The inscription is now in the Istanbul Museum.) Hezekiah's tunnel is an impressive engineering enterprise. Even today, some of the accomplishments still raise questions as to how they were achieved. Among the intriguing questions are, for example, how the workers had enough air during the work, how the two groups were able to meet, and how they were able to maintain such a shallow sloping angle.

Water Technology in the Andes

Kevin Lane

McDonald Institute for Archaeological Research,
University of Cambridge, Cambridge, UK

In this entry I describe ancient water technology in the Andes, South America, insofar as it pertains to economic activity. What I do not do here is describe the exclusively ceremonial or ritual uses of water (Glowacki & Malpass, 2003; Lumbreras, González, Lietaer, & Solís, 1976), although water, technology, and ritual do often go together in the Andes (Salomon, 1998; see also, de Avila, 1999 [1598?], p. 419, for an ethnohistoric example). Furthermore, given the geographical extent of the Andes, I focus mainly, though not exclusively, on water management infrastructure in the Central Andes, rather than that found beyond this area, such as the *bordos* – humped earth field boundaries that facilitated irrigated water conduit and retention – of the Catamarca region of Northwestern Argentina (Salminci, Tchilinguirian, & Lane, 2014) and complex causeway and canal network systems of the Amazon such as the Llanos de Moxos (Erickson, 1980, 2008). I should also mention that pre-Hispanic water technology, as applied to farming and herding in the Andes, was generally more varied and productive in the past than at present.

Water technology in the Central Andes can be roughly divided geographically into coast and

highland. Although there were some commonalities in the technology used in both areas, for instance, irrigation canals, there were substantial differences that derive from fundamental dissimilarities in the landscape, peculiarities of water discharge, and its overall availability. The coast desert strip is mainly characterized by water flow, rather than water storage, as seen in features such as irrigation canals, filtration galleries, and diversion embankments, which feed into a system dependent on floodwater and irrigation farming.

The highlands, with its vertical gradients, narrow valleys, and highland alpine *pampas*, favor technologies that emphasize water storage. Coastal water technology is also primarily targeted towards agricultural production, with the possible exception of *lomas* agropastoralism on fields and pastures located on the westernmost outlying hills of the Andes (c. 200–800 m). Agropastoralism along the *lomas* of the central and southern coast is sustained by the endemic winter fogs, known as *garúa*, that prevail in this area (Denevan, 2001; Engel, 1973). Meanwhile, the highlands display a more varied retinue of technological features that have so far eluded simple categorization into solely agricultural production. Indeed, in many cases highland water technology can serve the interests of both farmers and herders as part of a longstanding agropastoralist tradition (Lane, 2006b). Examples of this are the *q'ochas* (Flores Ochoa & Paz Flores, 1986; Flores Ochoa, Paz Flores, & Rozas, 1996) and the artificial *bofedales* (Lane, 2009; Palacios Rios, 1996) described in greater detail below.

Water technology on the coast has been studied intensely (e.g., Billman, 2002; Farrington, 1980; Kosok, 1965; Ortloff, 1993, 1995; Park, 1983; Rostworowski, 1998), while the highlands have merited much less attention. This was a concern already mentioned by Sherbondy (1969, p. 188) in the late 1960s. The reasons for the general paucity of studies into highland water technology are various, ranging from difficulty of access through to the low visibility of these features in the rugged terrain. This bias, which has existed since the time of the first Spanish chroniclers, has only started to be addressed from the

Water Technology in the Andes, Table 1 Main water technologies addressed herein

	Category	Type	Description
Water technology		Terraces	Artificial steps or benches on sloped terrain
		Irrigation canals	Canals distributing water to fields and land features
		<i>Puquios</i>	Underground filtration canals
	Dry	Pond fields (<i>Q'ochas</i>)	Sunken pond fields (highlands)
		Sunken gardens	Artificially depressed land plots
		<i>Camellones</i>	Raised field cultivation fields
		Water dams	Artificial lake
		Water reservoirs	Artificial pond
	Wet	Artificial <i>bofedales</i>	Irrigated moorland
		Silt dam	Large artificial silt trap
		Silt reservoir	Small artificial silt trap or silt terrace

latter half of the twentieth century onwards in the form of pioneering work into highland terracing, or *andenes* (Bonavia, 1967–1968; Donkin, 1979; Treacy, 1994a); raised field systems, also known as *waru-waru* or *camellones* (Erickson, 1986; Erickson & Chandler, 1989); pond fields, also known as *q'ochas* or *cochas* (Flores Ochoa & Paz Flores, 1986; Flores Ochoa et al., 1996; Rozas, 1986; Valdivia, Reinoso, & Mujica, 1999); and artificially irrigated moors, commonly referred to as *bofedales* (Lane, 2009; Palacios Rios, 1977, 1981, 1996). Nevertheless, there is still a substantial amount of work to do.

For the purposes of this entry, I divide water technology into two main types, *dry* and *wet*, in which *dry* designates technology in which water is a periodic component - such as in terraces and irrigation canals – whereas *wet* technology is reserved for those features for which water is an integral part of the technology, as in dams and reservoirs (see Table 1). A further, general consideration to reflect on is the importance of geological storage inherent in many of these technologies. For instance, water storage in artificial dams and reservoirs can also aid in the replenishment of natural aquifers thereby contributing to the water levels within the overall system.

Dry Water Technology

The main dry water technology systems found in the Andes are terraces; irrigation canals; sunken

gardens, otherwise known as pond fields, *q'ochas*, or *qochawiñas*; *puquios*; and sunken gardens. These are treated in turn below.

Terraces

Cultivation terraces, or *andenes*, are a water-using technology based around the creation of a series of level “steps” on otherwise sloped gradients of hills, ridges, and mountains. In the New World, terracing has a long tradition that covers North, Central, and South America (see Donkin, 1979, pp. 23, Map 22.21). In South America their distribution is mainly concentrated along the central Andean area, the dry Pacific coast, upwards into the semiarid western Andes and through to the cloud forest clad flanks of the eastern cordillera towards the Amazon.

Originally the earliest terracing in the Central Andes had been dated to around 500 BC (Donkin, 1979, p. 17), but more recent data has pushed the earliest known terraces to the Preceramic period c. 2480–2320 BC (Brooks, 1998). Whatever their antiquity the use of terracing was already widely established by the Middle Horizon (AD 700–1100), having by then spread substantially throughout the Andean region (Finucane, 2009). It is also widely recognized that terracing reached its apogee under the Inca Empire during the Late Horizon (AD 1438–1532) (Bonavia, 1967–1968, p. 270).

Donkin (1979, p. 22), in his seminal work on terracing in the New World, claims that 95 % of known terraces are found in either semiarid or arid

environments, which in turn means that the vast majority of these have to be irrigated. In the Andes the terraces on the western slopes are generally noted for being almost exclusively irrigated (Denevan, 2001, p. 183), hemmed as they are by the lower, drier western cordillera and the coastal desert. The terraces closer to the Amazon Basin are more likely to be rain fed given the higher degree of precipitation. Treacy (1994a, pp. 42–45) has identified four main functions fulfilled by terraces:

1. Platform for deep soil matrix which facilitates cultivation
2. Control of erosion
3. Creation of a sustainable microclimate
4. Control of humidity

It is worth describing these four aspects in some more detail as they are factors that are often highlighted by other water technology types, for instance, silt reservoirs (1–4), sunken fields (3, 4), and *camellones* (1, 3, 4). The main disadvantage of terracing is that the overall area of cultivation is somewhat reduced through their construction (Denevan, 2001, p. 183). Nevertheless, the advantages accrued means that the density of cultivation on terraces more than compensates for this partial loss of land surface.

The deepening of the soil matrix (1) allows for an extension of cultivation into areas that are either too steep or too rocky for normal agriculture. In turn terracing allows for the control of erosion along the otherwise heavily soil-depleted slope areas. This second function, control of erosion (2), is normally recognized as the most important function of terraces in the highlands, as it provides nutrient-rich soils while also helping alleviate the impact of the floods and mud avalanches (*huaicos*) endemic to these tree-denuded uplands.

The creation of a distinct microclimate (3) in which the relative temperature is ameliorated in respect to frost is especially important in the highlands, as it allows for the possibility of successful cultivation of certain crops at heights from which they would normally be precluded. Maize has usually been the favored crop in any consideration of cultivation arising from

temperature control (Earls, 1986). There are suggestions that animals might have been fed on the leftovers found in the fields after the gathering of the maize harvest for the Late Intermediate period (AD 1000–1480) along the north-central coast (Jones & Bonavia, 1992) and for Chavin de Huantar (900–200 BC) in the highlands (Burger & van der Merwe, 1990).

The last major function of terraces was the control of humidity (4). The availability of a flat surface, with deep soil and retaining stone wall, facilitates the accumulation and storage of water. This is achieved primarily through blocking the natural flow of water downhill occasioned by the construction of terraces. The existence of a deep soil matrix allows for the roots of plants to take deep root raising water levels that can be advantageous during periods of water shortage. Level surfaces also allows for a more symmetrical distribution of irrigated water. Many terraces are constructed of fieldstone and have an inner layer of permeable gravel or rock; this allows for the adequate drainage of excess water, which means that terraces are not water saturated, thus limiting the possibilities of drowning seeds and seedlings (Bonavia, 1967–1968, p. 231).

Denevan (2001, pp. 175–180; see Fig. 1) has identified five main types of terracing for the Andes: check dams, cross-channel terraces, sloping field terraces, bench terraces, and broad-field bench terraces. The first two involve direct water flow from streams, while the other three, especially the last two, are normally irrigated by canals. Check dams and cross-channel terraces will be discussed later in the context of *wet* water technology.

Sloping Field Terraces

Denevan (2001, p. 176) categorizes sloping field terraces as the most common form of terracing to be found across the Andes, usually in side valleys away from rivers or intermittent streams. Donkin (1979) has recorded them across the Andes from Argentina and Chile through to Ecuador. Sloping field terraces are built along the natural slope with soil accumulation occurring behind a retainer wall. Although the cultivation zone itself is sloped, the terrace wall acts to level the slope

Water Technology in the Andes, Fig. 1 Five types of terracing (From Denevan (2001))

through soil accumulation, allowing for control of erosion, water runoff, and moisture retention.

Sloping field terraces are usually partitioned into discrete parcels incorporating sidewalls; these can act as conveyors or deflectors of water flow. Sloping field terraces can contour the hill-sides, breaking them up into small field units (Lane, 2006a) perhaps suggesting slow construction over time. In other cases such as in Tarma, the terraces are regularly patterned suggesting a coeval, perhaps centralized construction (Denevan, 2001). Overhead feeder canals sometimes irrigate these terraces, although the vast majority sustain themselves on the yearly rains,

localized springs, or slope seepage. These features are therefore not regimented into equidistant parallel strips but can occur haphazardly along a mountain flank. The vast majority of these terraces have been documented for the areas above 3,500 m. At this height there is usually enough rainfall for at least one crop a year (Denevan, 2001, p. 177).

Bench Terraces

The classic image of Andean terracing is that of bench terraces, variously known as *andenes*, *patasi*, *bancales*, and *takhanes* (Fig. 2). The most characteristic of these terraces are built of

Water Technology in the Andes, Fig. 2 Bench terraces, Santiago River, Upper Ica Basin, Peru (Photo by author)

close-fitting stone retaining walls usually between 1 and 5 m in height. They tend to occur along valley sides and are usually arranged in parallel vertical rows. The walls slope inwards thereby presenting a leveled surface apt for cultivation that is usually fed by some form of integrated irrigation system.

Treacy (1994a, p. 129) describes a well-documented integrated irrigation system at Coporaque, but they are ubiquitous across much of the Central Andes. Some bench terraces are banked with earth rather than the more sturdy stone walling (Denevan, 2001, p. 179). A number of these terrace types have been excavated (e.g., Bonavia, 1967–1968; Donkin, 1979; Schjellerup, 1986; Treacy, 1994a) showing what Denevan (2001, p. 179) describes as a series of drainage horizons. These are constructed in the Upper Mantaro Valley of an initial cobble layer lain over a buried topsoil; this cobble layer is in turn overlain by a “modern” humic topsoil which retains moisture. Excess water is quickly drained through the cobble layer outwards from the terrace (Bonavia, 1967–1968, pp. 230–233). Schjellerup (1986) has identified a similar

internal construction for the terraces at Atuén in the Chachapoyas Region and Keeley (1985) for the Cusichaca Valley. These two examples, among others, seem to indicate that bench terrace architecture shares broad similarities across a vast geographical region.

Broad-Field Terraces

Broad-field terraces are similar in composition to bench terraces, with the added difference that the cultivation surface is significantly wider, sometimes exceeding 100 m; while retention walls tend to be lower (Denevan, 2001, p. 180). Geologically, therefore, they are found in different environments to the traditional bench terrace described above favoring more undulating and gentler sloped valleys such as those in Northwestern Argentina or the riverine banks such as along the Vilcanota River valley near Cuzco.

Irrigation Canals and Puquios

Irrigation canals are among the most basic water feature; their function is simply to move water from where it is abundant to where it is needed (Fig. 3). This though belies the potential

Water Technology in the Andes, Fig. 3 Stone-lined canal, Cachi Valley, NW Argentina (Photo by author)

complexity of irrigation networks, especially in hyperarid places such as Puna de Atacama on the borders of Argentina, Bolivia, and Chile (Quesada, 2006), although canal networks in the Central Andes can be equally extensive, complex, and ancient (e.g., Dillehay, Eling, & Rossen, 2005; Farrington, 1980; Guillet et al., 1987; Mitchell & Guillet, 1994; Sherbondy, 1994; Treacy, 1994b).

Irrigation canals have a long history within the Andean region, especially along the dry coastal valley. Claims have been made for irrigation canals by around 3400 BC and perhaps as far back as 4700 BC in the Zaña Valley along the north coast (Dillehay et al., 2005; Dillehay, Rossen, & Netherley, 1997). Indeed, the whole of the coast presents a series of small to large canals crisscrossing the valleys and sometimes across valleys. It was partially the monumental scale of this endeavor in the Andes that first suggested to

Wittfogel (1957) and Steward (1955) the possibility of centralized states based around the organization of labor for the maintenance of complex irrigation canal systems. For instance, the Moche (AD 1–650) and the Chimú (AD 1100–1470) are characterized by their hydraulic expertise and extensive canal building (see Ortloff, 1995; Park, 1983; Pozorski & Pozorski, 1982).

Away from the coast, the highlands also demonstrate substantial evidence for widespread use of irrigation canals. The scale of irrigation canal use in the highlands is lower as a consequence of the more generalized availability of rainfall than on the coast. Also, the lack of flat, irrigable land surfaces means that irrigation is limited to bringing water from aquifers to fields and terraces. Even so, the magnitude of these networks can be impressive even at the local scale. In the modern Chaclacayo *microcuenca* (c. 140 km²) located in the Ancash highlands, 15 modern canals have been identified covering a distance of 58.3 km across the whole area (Junta de Desarrollo Distrital de Pamparomás, 2000). This pattern is replicated across the Central Andes with the caveat that in the past these networks were both more extensive and better organized (Denevan, 2001; Gelles, 2000).

The important role that irrigation canals hold within the social fabric of Andean highland communities should not be underestimated; Gelles (2000) and Trawick (2003) have attested to the enduring centrality and the social obligations that go hand in hand with canal maintenance and equitable distribution of water. Archaeologically, irrigation canals have been relatively understudied in the highlands, other than around the Titicaca Basin and the Inca heartland of Cuzco (see Erickson, 1993; Kolata & Ortloff, 1996). One reason for this is that their visibility is low when compared to that of terraces and other water technology and the fact that subsequent reuse can obliterate earlier, older use. Still, both in the highlands and coast they represent the most important linking component between the different types of water technologies.

Farrington (1980, p. 289) has identified two main types of canals: stone lined and unlined canals. The main distinction between these two

types of canals is that the stone-lined canals are usually the *acequia madres*, or main feeder canals, the core of the irrigation system, from which more localized outtakes, or *acequia secundarias*, then disperse the water to individual plots and terraces. The latter category are usually made up of earthen or sod-banked canals, being much more transient constructions their course can change with relative frequency depending on fallow seasons and shifting cultivation patterns. Cobble or slab-lined canals are usually more static and permanent features and thus easier to observe and record archaeologically. The volume of water from streams is controlled and then distributed by means of sluice gates (*boca tomas*); *boca tomas* are also sometimes cut into *acequia madres* so as to facilitate subsequent water distribution throughout the irrigation network.

Denevan (2001, p. 146) has recognized the basic engineering functions of canals as being:

1. The deliverance of water at the point of need
2. To do so in the most efficient manner with a minimum of canal scouring, sedimentation, or atmospheric transvaporization

Transvaporization is a serious problem in the coastal valleys. Kus (1984) in particular, recognized this in the large and wide Moche- and Chimú-period canal systems. A way around this problem is the use of subterranean canals to transport water; their underground nature makes them hard to detect archaeologically. Nevertheless, their presence has been uncovered, for instance, in Northwestern Argentina (Páez & Giovannetti, 2014) where they crisscross the cultivation fields. Although coastal canals demonstrate an exceptionally high degree of hydraulic complexity, expressed explicitly in their scale and monumentality (Oré, 2005; Ortloff, 1995), this should not blind us to the fact that the indigenous people of the highlands demonstrated a similar awareness of hydraulic expertise in their constructions, albeit usually at a different scale of monumentality to that found on the coast.

Furthermore, there is evidence to suggest the construction of large canals in the highlands,

bringing water from the summit of the cordillera (*puna*) down to the mainly agricultural lower-valley (*yunga*) areas and even all the way down to the coast. This is the case with the Huiru Catac, or Tokanka, Canal of the North-central Jimbe Valley (Gambini, 1983–1984; Villafana Avila, 1986), and the South-central Achirana Canal (Oré, 2005). Still, the importance of these large canal systems in these areas should not be overestimated, given that the highlands usually present extensive interconnected irrigation networks of smaller canals rather than these monumental endeavors, more common to the coast.

One final technology that in some way incorporates the concept of canals, referred to aqueducts and filtration galleries, is those described in detail for the Nazca region of the South-central Andes (Schreiber & Lancho Rojas, 1995, 2003) although their presence has been observed south in Chile and as far north as the Santa Valley in the North-central Andes, as well as in the highlands (Barnes & Fleming, 1991, p. 51). In the South-central Andes these aqueducts and *puquios*, literally canals and wells, are probably Nazca period (100 BC – AD 650) features, with possible expansion of the system under Spanish colonial rule (post-AD 1532) (Barnes & Fleming, 1991; Schreiber & Lancho Rojas, 2003).

This technology comprises a series of vertical and horizontal trenches (aqueducts) and tunnels (*puquios*) that tap into phreatic aquifers, especially in sections of coastal valleys – such as in the Nazca area – where surface river water periodically disappears underground. This water is then brought to the surface to irrigate agricultural land. Water availability in these features fluctuates according to the annual discharge in the rivers (Schreiber & Lancho Rojas, 2003).

Pond Fields and Sunken Gardens

Pond fields, *q'ochas* or *qochawñas* (Fig. 4), referred to generically from hereon in as *q'ochas*, are a relatively recent discovery (Flores Ochoa & Paz Flores, 1986; Flores Ochoa et al., 1996; Rosas, 1986; Valdivia et al., 1999). These comprise differentially sized, shallow sunken fields linked by canals that feed water to these depressions. They are farmed by rotation

Water Technology in the Andes, Fig. 4 *Q'ochas*
from Erickson (2000)

allowing the pond fields to lie fallow for between 3 and 5 years after a harvest. During the fallow years the *q'ochas* are used either as drinking ponds, or as reservoirs for animals and people, or to grow fodder for animals. This last point is important as it serves to emphasize the dual nature –farming and herding – of many of the water features in the highlands.

In a similar fashion to the raised fields discussed below, *q'ochas* are important for controlling water and seasonal runoff, for nutrient capture, and for aquaculture, as well as providing an improved microclimate in which to practice agriculture. Additionally, *q'ochas* provide an

important source of sod for construction purposes and are sometimes used for the preparation of freeze-dried tubers, known locally as *chuño*. Generically, both raised fields and pond fields address the aforementioned problems of nutrient retention and soil conservation, concerns that are also present in the construction and maintenance of terraces.

Along the northern coast similar structures known as sunken gardens, *hoyas*, *wachaques*, or *mahamaes* (Fig. 5) have been identified (Parsons, 1968; Rowe, 1969; Smith, 1979). Inland on these coastal valleys, these 2000-year-old, agglutinated sunken gardens tapped phreatic water sources to

Water Technology in the Andes, Fig. 5 Sunken gardens from the Casma Valley, Peru (Kosok, 1965)

provide rich and shaded agricultural land while also benefitting from periodic flooding such as the pond fields above (Knapp, 1987, *contra* Parsons & Psuty, 1975) which in effect also controlled the flooding episodes from the nearby river. It is now widely acknowledged that this technology was both productive and widespread (Shimada, 1994, p. 53).

Wet Water Technology

In this section we consider those features in which water is either an integral part – as in the case of reservoirs and dams – or through which water flows constantly or almost constantly. Within this last category we include two important features of water and field technology: raised fields, *camellones* or *waru-waru*, and artificially irrigated high-altitude moorlands or *bofedales* (known as *vegas* in Argentina and Chile). Both types of water technology exist within the same area, the Titicaca Basin region, with *camellones* and artificial *bofedales* present across a large area of the Andes. *Camellones* occur from French Guyana across to Colombia down to Bolivia (e.g., de la Torre & Burga, 1986; Plazas, Falchetti, Sáenz Samper, & Archila, 1993),

wherever the predominant ecozones are *páramo* and humid *puna* (Custred, 1977), while artificial *bofedales* are found throughout areas in which camelids were herded in the past (e.g., Lane, 2009; Palacios Rios, 1996; Quesada, 2010). Artificial irrigation of pastureland is still practiced nowadays, albeit to a lesser scale than formerly and mainly through the diverting of water onto silt-clogged areas using temporary sod canals (Fig. 6).

In the past large-scale construction of dams and reservoirs, for water storage but also for trapping silt, allowed the creation of large areas of artificial *bofedal*. While water reservoirs and dams are pretty self-explanatory, silt reservoirs and dams require further explanation. In essence, they constitute differentially sized silt catchments, otherwise known as check dams or cross-channel terraces in the literature (Denevan, 2001, pp. 175–180; see Fig. 1). Their presence in the Andes has only recently been documented (Lane, 2009) and they represent a variation on the artificial *bofedales* mentioned above. Denevan (2001, p. 157) and Scarborough (2003, p. 59) have previously argued that there is little evidence for dams and reservoirs – also known as *represas*, *reservorios*, and *estanques* – in the Andes, yet recent studies confirm that their presence was

Water Technology in the Andes, Fig. 6 Modern sod-canal feeding artificial *bofedal* or *vega*, Cachi Valley, NW Argentina (Photo by author)

much more ubiquitous across the Andes than has been commonly acknowledged (e.g., Herrera, 2011; Lane, 2009; Lanzelotti, 2011; Salomon, 1998).

Raised Fields

Although raised field – *camellones* or *waru-warú* – systems are found across a large area of the Andes (Herrera, 2011, Fig. 1), the most detailed studies have been conducted on those from the Titicaca Basin (see de la Torre & Burga, 1986; Erickson & Chandler, 1989; Kolata & Ortloff, 1996; Smith, Denevan, & Hamilton, 1968). These raised fields (Fig. 7) are a series of large, elevated cultivation platforms constructed in areas of waterlogged soils or areas prone to annual flooding. In between these platforms there are a series of shallow ditches, forming a ridge and furrow pattern. The furrows are permanently inundated with water from adjacent canals. In a similar fashion to the terraces above, raised

field systems have certain advantages over normal fields, summarized below:

1. Soil improvement
2. Greater control of annual flood and rainfall waters
3. Capture and reutilization of sediments and soil nutrients
4. Ameliorated microclimate promoting better plant growth conditions
5. Creation of wetlands, enriching of local flora and fauna

Together these five factors make agriculture in this *puna* environment viable. Indeed, in the treeless and sloped expanse of the Andean *puna*, soil leeching on normal fields is a constant problem that adversely affects animal, plant, and human communities. In turn this leads to environmental deterioration and eventual abandonment if measures are not taken to artificially replenish and maintain the soils (Young, Leon, Cano, & Herrera-MacBryde, 2005; Young, León, & Herrera-MacBryde, 1997). In a similar fashion to terraces, raised fields can proportionally increase productivity compensating for the land lost to flooding (Erickson, 1993).

Water Dams

As previously mentioned, water dams have received little attention. Yet their presence has been increasingly recorded across huge areas of the Andes. Perhaps a reason for their absence from the literature is twofold. First there is the fact that the majority of these dams are located in the generally more inaccessible upper reaches of the highlands; and second, many of these pre-Hispanic features are increasingly being destroyed by modern micro-dams (Lane, 2013). Invariably the majority of these high-altitude dams are located in the westernmost mountain range of the Andes (although see, Herrera, 2011, pp. 64–65, for a notable exception to this rule), given that this is a non-glaciated range and thus lacks a permanent source of water.

Aside from scattered evidence of highland dams reported by Donkin (1979, p. 105) near Arequipa in the South-central Andes; Salomon

Water Technology in the Andes, Fig. 7 Raised fields, Tiahuanaco, Bolivia (Photo by author)

(1998) in the Huarochiri Province of the Central Andes; and Gambini (1983–1984, p. 111) in the Jimbe Valley of the North-central Andes and increasing evidence for these structures from as far afield as Argentina (Cornejo, 2001; Lancelotti, 2011), the first major study into water dams appeared only during the last decade (Lane, 2006a). Here, in a survey of *c.* 80 km² of the Cordillera Negra of the Ancash Province, 18 pre-Hispanic water dams were identified at areas between 4,100 and 4,800 m. At this height there is little sedimentation of lake basins given that the maximum height of the western mountain range is *c.* 5,200 m. In the dams built at this altitude, water is gathered during annual rains and from springs. Interestingly, these features are located in areas where the underlying geology is mostly basaltic andesite which is a relatively hard, though brittle rock with limited porosity. Fissures in the rock though facilitate permeability leading to the enhancement of underground aquifers.

These structures are gravity dams given that their weight and mass is what holds back the water (Fig. 8). The dam walls are constructed of large stone blocks, with the inside of the structure infilled by compacted earth and stone. They are roughly triangular with a wide base tapering towards a narrower crest. By these means it counteracts the water pressure that is exponentially greater at the base of the dam. These structures

are usually anchored to natural rock outcrops, adding greater solidity to the construction. A series of sluices cut into the dam wall regulate water flow. These dams come in very different sizes, from 5 m to over 100 m across and capacities, ranging from *c.* 6,000 m³ to *c.* 700,000 m³ (Lane, 2009, pp. 175–176).

Water Reservoirs

Water reservoirs (Fig. 9) are mentioned and pictured in ethnohistoric sources (see Guaman Poma de Ayala, 1993 [1615], p. 937) and have been extensively recorded for the coastal areas in association with irrigation agriculture (e.g., Farrington, 1980; Kosok, 1965; Netherly, 1984) they are also known as “holding ponds” (Vreeland, 1986). Similarly, in the highlands they have been reported by Donkin (1979) and Gambini (1983–1984) among others. Water reservoirs are increasingly targeted by nongovernmental organizations as a cheap and efficient means towards localized water storage (see Venturi & Villanueva, 2002).

This close association between cultivated fields and reservoirs means that these features are usually located within agricultural zones. Reservoirs are generally round, ovular, or roughly rectangular and vary between 10 and 15 m in relative diameter or length, holding roughly between 100 and 300 m³ of water. Construction is of a rough coursed-stone internal wall

Water Technology in the Andes, Fig. 8 Water dam, Cordillera Negra, Ancash Highlands, Peru (Photo by author)

and either a similar external wall or an earthen embankment. Reservoirs are enclosed constructions in that they enclose a specifically bounded area on all sides. A canal, either earthen or stonewalled, acts as a feeder, diverting water towards the reservoir (Fig. 10). These canals have to be periodically cleaned or recut as sedimentation is a serious problem for these features.

Artificial Bofedales

An Andean *bofedal* is a poorly drained area of moorland on which plant communities favorable for the rearing of camelids grow, especially for alpacas (*Lama pacos*), the less hardy of the two camelid domesticates. They are also known as *distichia* moors, wet pastures, and high-altitude moorlands (Aldenderfer, 1998; Dransart, 2002; Kuznar, 1995). These natural habitats represent an extremely rich pastoral resource and are thus highly coveted by local communities (Browman, 1990). For these reasons some communities have constructed artificial *bofedales* fed by irrigation canals to supplement the naturally occurring

areas of moorland (Palacios Rios, 1977, 1981, 1996). Irrigated *bofedales* appear across a large geographical area (e.g., Carhuallanqui, 1998; Kuznar, 1995); furthermore they are mentioned ethnohistorically (Guaman Poma de Ayala, 1993 [1615], p. 780) and attested archaeologically (Erickson, 2000, p. 343; Quesada, 2010, p. 88) underlining their antiquity and present importance across the Andes.

The majority of the ethnographically recorded artificial *bofedales* are small- to medium-scale affairs reflecting a household-type economy, although in some cases the area turned over to artificial *bofedal* via irrigation can be truly massive. For instance, among the Chichillapi communities of Puna, an area of 2,200 ha. was turned into an artificial *bofedal* (Palacios Rios, 1977, 1981, 1996). Here at Chichillapi the main area of artificial *bofedales* lies at and above 4,000 m, along the Chila River, and belonged to the Laka community of agropastoralists. Riverine water was diverted and dispersed towards the sides of the valley by two large outtake canals called

Water Technology in the Andes, Fig. 9 Water reservoir, Cordillera Blanca, Ancash Highlands, Peru (Photo by author)

hach'a irpas which directed the water towards the margins of the *bofedal* area. These canals run along the left and right edge of the *bofedal*; the canals were between 1.7 and 2.2 m wide, 0.6 and 0.8 m deep and run some 9–17 km. The canal walls were banked with reinforced sods that created a living embankment along the canal's length. A series of shorter feeder canals called *hisk'a irpas* then distributed the water more locally creating the *bofedal* proper. This system of irrigation is similar in essence to that employed by farmers to irrigate their own plots of land using canals.

Bofedales are fragile environments that require constant maintenance by households and communities who clean them once a year after the rainy season. Given the large areas of dried-up *bofedales*, it is likely that there were many more *bofedales* in use during the pre-Hispanic period when powerful agropastoralist communities and polities controlled the highlands (Erickson, 2000, p. 343). Apart from the obvious

grazing advantage accrued for animals, *bofedales* are also important areas for the retention of organic silts and for geologic water storage (Fairley, 2003). Given the different geological and geographical environments in the Andes, it is evident that regional differences existed in artificial *bofedal* construction. This can be seen in the evidence for silt dams and reservoirs from the north-central highlands (Lane, 2006a, 2009).

Silt Dams

Recent studies (Lane, 2006a, 2006b, 2007, 2009) into hydraulic technology in the Ancash highlands have uncovered evidence for a distinct form of wetland or *bofedal* creation and capture. Rather than the household scale of *bofedal* construction described above, the scale of *bofedal* construction here is beyond that even of the Chichillapi herders of Puna (Palacios Rios, 1977, 1981, 1996) to encompass truly monumental scales.

In the case study from the Ancash highlands, five silt dams created over 372,027 m² of artificial

Water Technology in the Andes, Fig. 10 Schematic of pre-Hispanic water reservoir

bofedal, although this does not include the areas with preexisting natural *bofedal* and those created via the use of silt reservoirs described below. Outwardly, these dam-like structures bear striking similarities, including size, to the normal water dams described above, in that they were constructed of double-faced walls, infilled with compacted earth, stone, and clay, making an impermeable barrier behind which sediment and water are stored (Fig. 11). The central part of many of the dams was reinforced by step-like walling, probably reflecting the added pressure present in this area of the structure. Unlike the water dams, though, the silt dams were located much lower down the altitudinal ladder of the Andes, occurring normally between 3,800 and 4,450 m.

Freisem (1998) has interpreted them as secondary erosion dams used in the prevention of periodic silt and loam floods that afflict fields and settlements throughout the Andes. Similar structures have also been identified along the coast, such as in the Chao Valley (Brooks, Willett, Kent, Vasquez, & Rosales, 2005). While this interpretation is very plausible, it is likely that these structures had a dual purpose. So that alongside checking erosion discharges, these structures provided silt platforms that facilitated the creation of a *bofedal* for use in grazing. Furthermore, accumulation of silt-rich sediment behind these

structures provided a bank of material for use in nutrient-depleted terraces.

Unlike water dams, silt dams are not necessarily anchored onto rock and they usually have only one discernible outtake sluice located along the base of the structure, usually at its center. The basic principle governing the silt dam is that of geologic water storage (Fairley, 2003); in this case the accumulated soil basin acts as an aquifer in which water is both stored and purified through the soil. The soil also acts a water barrier to water seepage therefore, the sluice should be viewed rather as a sieve that siphons excess water out of the basin while the soil retains enough saturated moisture for the growth of *bofedal*-type vegetation.

Silt dams would have been the result of a process of construction, accretion, and maintenance. In the main, the initial silt basin would probably have been small and would have grown slowly through silt accumulation during the annual rains, a system of accretion known as varve formation (Leet, 1982).

Silt Reservoirs

Another technology facilitating the creation of *bofedales* is that of silt reservoirs, otherwise known as check dams or cross-channel terraces (Denevan, 2001). A detailed case study describes their presence in Ancash highlands of the

Water Technology in the Andes, Fig. 11 Silt dam, Cordillera Negra, Ancash Highlands, Peru (Photo by author)

North-central Andes (Lane, 2006a, 2009) but there is increasingly evidence to suggest they existed across a large area of the Andes including the North-central coastal Jequetepeque Valley (Dillehay & Kolata, 2004) and the South-central highland Colca Valley (Treacy & Denevan, 1994). In these two cases though, check dams and cross-channel terraces are used primarily for agriculture in a similar fashion to the terraces discussed above. Further cases of cross-channel terraces have been documented by Denevan (2001) quoting Regal's work in the Chiva River Basin and by Donkin (1979) reporting on Ecuador, Chile, and Northwestern Argentina.

In the case of silt reservoirs of the Ancash highlands, their location at the *suní-puna* transition above 3,900 m – and up to 4,400 m – precludes a substantial agricultural *raison d'être* given the enduring cold and harshness of the environment at this altitude, suggesting rather their use as stepped *bofedal* terracing. This is similar to the cross-channel terraces recorded in the area of Socaire along the edge of the Chilean Altiplano

at around 3,700–3,900 m (Donkin, 1979, p. 126). The Ancash silt reservoirs are open features usually semicircular or horseshoe shape ranging between 7 and 20 m in length, with an average height that ranges between 60 and 200 cm. These features tend to be wider at the center of the reservoir, varying between 60 and 120 cm, although some of the larger constructions reach widths of up to 160 cm across the center (Fig. 12).

These features are of double-faced stonewalling, infilled with compacted rock and clay. They are set perpendicular to the water, impeding its uninterrupted flow thus acting as a silt trap and as an erosion barrier to the annual hill-wash episodes and high-energy highland discharges that occur periodically in these landscape. In turn the entrapment of silt permits the creation of small *bofedal* microenvironments behind the walls. As with the silt and water dams, silt reservoirs utilize, where possible, natural rock outcrops lending further stability to the structures. The primary functions of these structures are erosion control, silt entrapment, water

Water Technology in the Andes, Fig. 12 Silt reservoirs, Cordillera Negra, Ancash Highlands, Peru (Photo by author)

catchment, and subsequent distribution with the added result of creating a small area of *bofedal*.

Similar to check dams these reservoirs are positioned across the breadth of small highland pampas that form in ravines. In these broad sloping areas, the silt reservoirs are positioned so as to distribute water across the widest extent possible thus providing the maximum possible platform on which to develop the microenvironment necessary for a *bofedal* (Fig. 13). As with the silt dams described above, these features have a drainage sluice, usually along the bottom and center of the structure; this helps drain excess water from the structure.

Conclusion

Water is a perennial subject matter whose relevance and importance is constantly growing in a world where pollution and scarcity increasingly undermine its availability and characteristics (Gleick et al., 2014). Water technology is seen as a means of harnessing this scarce resource. Here we have addressed a number of technologies employed by pre-Hispanic societies towards controlling and managing water and in many instances, soil, for the general improvement of local environmental and economic conditions.

And this is the crux of the matter; millennia of development in water technology in the Andes rendered this area into a veritable series of managed landscapes (Denevan, 2001). Nevertheless, this should not blind us to the fact of collapse or maladjustment of some of these technologies in the past (see Lentz, 2000; also Graffam, 1992, describing the decline in the use of raised field systems during the pre-Hispanic period); it is also a truism that, in the main, these technologies adjusted themselves exceptionally well to the exigencies of this land. This situation changed under Spanish colonial and subsequently republican rule so that many of these technologies – sunken gardens, *q'ochas*, and silt reservoirs – were only partially maintained or not maintained at all leading invariably to degradation, erosion, and abandonment of vast tracts of the Andes.

Although this can be visibly seen, for instance, in the number of abandoned terraces that litter the highlands, its effects on the coast are if anything even more obvious. Here modern agro-industry often emphasizes high water intake monoculture, such as asparagus (Lawrence, 2010) and artichokes, that drains local aquifers and demands labor resources not available locally. In turn this leads to a human exodus from the highlands to the coast and even to the creation of modern megacanal that siphon water from the highlands to the

Water Technology in the Andes, Fig. 13 Schematic part of a silt reservoir system (approximate scale 1:500). Silt reservoirs store and filter water through the accumulation of humid silty soils. As the water flows to these structures, sediments are dragged with it, which is then trapped by silt reservoir walls. At the same time water is diverted towards the sides of the valley that would not usually benefit from this water flow. This in turn slows the velocity of this water reducing erosion, lessening loss of silt. (1) Water flow is halted by a robust, almost lineal, wall behind in which silt accumulates. Excess water is diverted through a sluice at the base of the reservoir wall and through earthen canals towards two further interconnected silt reservoirs downslope; (2) behind the walls of these two interconnected silt reservoirs a medium-sized area of artificial *bofedal* is created; (3) excess water and silt flow from (2) are captured by a further lower-lying silt reservoir, associated with (4) with similar results to (2); (4) excess water from (3) finally reaches a small silt reservoir which acts as a filtration terrace or check dam to the whole system. A further small *bofedal* is created behind this structure

coast (as in the case of the Majes Canal in South-central Peru, see Boelens & Gelles, 2005; Gelles, 2000), culminating in the almost wholesale destruction of traditional methods and farming along the coast and its gradual decay in the highlands.

Efforts at preserving these traditions exist (e.g., Branch et al., 2007; Erickson, 1998; Kendall, 1994; PIWA, 1994), as do blueprints arguing for the continuation of traditional technology and its advantages for rural development (Herrera, 2011, 2013). Nevertheless, they have yet to make significant headway against the

predominant political ecology (Lane, 2013). A paradigm that de-incentivizes small-holder, local production (Mayer, 2002), through an increasing emphasis on large-scale (Meade, Baldwin, & Calvin, 2010), export market production especially along the coast. Given these circumstances it is imperative that every effort is expended in identifying and describing these ancient water technologies. On the coast many of the remaining vestiges of these have already disappeared; soon abandonment, dislocation, and disuse will do the same to those in the highlands. It is our duty to document these and the traditions that underpin them before they too cease to exist.

Weaving Cotton in Ethiopia and Nubia

Michael Gervers

Archaeological material finds provide invaluable information about the nature and source of textiles and textile fibres in Nubia in the early Christian era. In the half century since Griffith and Crowfoot first identified cotton among the textile fragments excavated at Karanog and Meroe, much more cotton fabric has been retrieved from the rescue excavations of early habitation sites along the Nile subsequently inundated by Lake Nasser; i.e., between Aswan in Upper Egypt and Wadi Halfa in northern Sudan. The oldest fragments identified as cotton have been dated to the Roman period and may be as early as the first century AD. The great majority are attributable to the late Meroitic period, ca. 200-ca. 330 AD, at which time cotton appears to have been the most commonly available fabric. The following period, from ca. 330 to ca. 550 AD, sees a swift

and remarkable change in the predominant textile fibre in the region. The use of cotton plummets and is replaced by animal fibre, largely camel's wool.

The quantity of cotton found in excavations of the Roman and late Meroitic periods has led many to conclude that the fibre reached Lower Nubia from the south, where it is thought to have been grown, since this area lies in the rain belt and could have provided the environment necessary for growth. However, no specific sites for cotton cultivation in Nubia and the Sudan at this period have been identified and in view of the chronology of the archaeological evidence, and of what is known of the political and economic situation and agricultural production of the period, there is good reason to suppose that vegetable fibres for textiles were not then grown in Nubia or even in the Sudan. Rather, the Nubians, lacking any such indigenous source of raw material, were obliged to import whatever they required either as cloth or raw fibre. These goods included linen, which, throughout much of the Middle Ages under the provisions of the *baqt* agreement, was one of the principal items received by the Nubians in exchange for slaves. The *baqt* was first formulated in the seventh century, by which time, in the absence of adequate supplies of cotton, the Nubians seem to have sought imported linen as an alternative. The cotton would have been *gossypium arboreum*, and its ultimate source would have been the west coast of India. How it reached Nubia is uncertain. It could have come via the eastern desert trade routes from such ports as Suakin on the Red Sea, or via the kingdom of Axum, which by 300 AD. enjoyed a thriving trade with India. The costs and difficulties of overland transport, however, make it more likely that cotton reached Nubia through the Roman world to the north via the Nile. Since the archaeological cotton remains from Nubia were not made from locally grown fibres, there can be little question of cotton reaching Ethiopia from the Sudan. One early reference which is universally accepted speaks of the direct importation to the Red Sea Axumite port of Adulis of cotton from India in the first century AD. The first

indication we have of the production of fine cotton cloth in Abyssinia occurs at the end of the thirteenth century in the commentary of Polo: "Good cotton and buckram cloths are woven here". If his source for the supply is accurate, one can reasonably conclude that by that time cotton cultivation and weaving was well established in the highlands.

Textiles, especially imported, have always been an expensive commodity. Their distribution through the ranks of a society depends directly on the geographical diffusion of the raw material, the quantities produced and the availability of mechanisms to spin and weave it into cloth. An Egyptian source for cotton grown in India would explain why a blue and white cotton tapestry decorated with Egyptian symbols was among the Meroitic finds from Qasr Ibrim. It would also explain why the cotton, if imported raw from India and locally spun, would appear different in texture from contemporaneous cotton cloth of Indian origin discovered at Palmyra. Cotton cloth woven in the humid atmosphere of India could be much finer than that produced in the arid climate of Egypt or Upper Nubia. The latter, if woven on the warp-weighted loom, as is supposed, would have to be much thicker and coarser to prevent it from breaking under the stress of the weights. Consequently, it would have appeared softer than the material from Palmyra and more like wool. When cotton became less available from the fourth century and was replaced by wool, the warp-weighted loom would have been all the more appropriate for weaving it. Weaving in Ethiopia today is carried out almost entirely on a pit-treadle loom, whose treadles are suspended in a hole in the ground. The weaver sits at the edge of the pit with his legs inside so that his feet can operate the treadles. The origin of this loom in Ethiopia is uncertain, although numerous writers have noted how closely it parallels the Hindu loom, and some suggest that the technology is the result of direct importation from the Indian subcontinent. Endrei believes this loom originated in India for the purpose of cotton weaving. The specific characteristics of the Abyssinian loom, according to Boser, are its

sturdy frame, the width of the comb and consequently of the cloth produced, and the depth of the pit. Boser goes on to say that regardless of how this loom got to Abyssinia, it did not spread thence to other parts of Africa. It did not spread, until recent times at least, even to southern and western Ethiopia. A close relative is the warp-weighted pit loom which is found frequently in Persia, Syria and Egypt where it was, and is, used particularly for weaving woollen, and in Egypt at any rate for weaving linen thread. It does not seem to be appropriate for weaving with a cotton warp as the strain placed by the weights on the thread would cause it to break. This restriction would explain the absence of the warp-weighted loom in Ethiopia, where cotton is by far the principal fibre used for weaving today. The technical association of the Ethiopian loom with cotton would also argue in favour of a common development, if not introduction, of cotton growing and weaving to the Abyssinian highlands.

Wei Boyang

Fabrizio Pregadio

Although many Chinese works relate the name of Wei Boyang to the origins of alchemy, nothing is known about him from a historical point of view, and his figure may be entirely legendary. Some sources, which place him in the second century, relate that he came from Shangyu (in modern Zhejiang) and transmitted his teaching to Xu Congshi, who in turn handed it down to Chunyu (alternative spelling: Shunyu) Shutong. The text deemed to embody the gist of this transmission is the *Zhouyi cantong qi* (Agreement of the Three According to the Book of Changes), a scripture in verses that is attributed to Wei Boyang. The commentaries usually interpret the “Three” as Heaven, Earth, and Man, or as Daoism, cosmology, and alchemy. The *Book of Changes* is the *Zhouyi* (or I Ching, also spelled *Yijing*), the renowned divination manual, which also includes a classical exposition of cosmology in its section commonly known in the West as “Great Treatise.”

The genesis of the *Cantong qi* is as obscure as its putative author. Current research tends to consider that an originally Han text on cosmology may have been elaborated into an exposition of alchemical doctrines, perhaps at different dates until the seventh century. The very few references to a *Cantong qi* before that time seem to refer to the original cosmological treatise, whose circulation may conceivably have

been restricted due to its association with an unofficial and proscribed body of writings propounding esoteric interpretations of the Confucian classics.

Since the late Tang, however, the *Cantong qi* began almost abruptly to exert a far greater influence in the history of Chinese alchemy than that of any other text. Hidden in the highly allusive language, and the thick layers of symbols and images that characterize this scripture, is an exposition of the doctrine that inspired a variety of commentaries (about 30 of which are extant) and other texts, written between the eighth and the nineteenth centuries, in both Daoist and Neo-Confucian traditions. One of the most well-known exegeses was written by the Neo-Confucian philosopher Zhu Xi, who commended the high literary quality of the text.

The *Cantong qi* would hardly be intelligible without recourse to the related literature. Although it was occasionally read as a treatise on cosmology, most commentaries agree that it articulates the theories found in the tradition of the *Book of Changes*, applying them to the alchemical work. The *gua* (trigrams and hexagrams) of the *Book of Changes* are used both to construct a cosmological model and, at the same time, to represent phases of the process performed by the alchemist. The various possible levels of reading of the text possibly mean that it was used within both the main traditions of ► [alchemy in China](#), i.e., *waidan* or “external alchemy” and *neidan* or “internal alchemy.”

- *Dja-yôbwê* (dja stone). Here the term refers to the contents; it designates what is contained in the package or *dja*. These original elements would be in stone and would be concerned with different realms of human knowledge deemed worthy of interest.
 - *Sika-yôbwê* (stone of gold) money. In this second case, the term describes a price or a monetary total. These elements would deal with economics, calculation, and mathematics.
 - *Nsangan-yôbwê* (stone of a fine). This term describes the price of a fine, a tax, or a tribute, and is concerned with elements of economics and finance.
 - *Ahindr-yôbwê* (proverb stone). This term evokes the notion of speech, thought, and discourse, the fields of literature and philosophy.
 - *Ngwa-yôbwê* (game stone). This term refers to the figures comprised of graphic signs. The exercise of reading or deciphering the signs was considered a kind of game, involving elements of imitation and intellectual training.

Weights and Measures in Africa: Akan Gold Weights

Georges Niangoran-Bouah

The subject of gold weights is complex and multidimensional. It can be understood only when placed in the context of its original cultural environment, which was linked intimately to gold for its physical substance and to the package (*dja*) in which it came for its sociocultural identity.

The Akan country, on the Gulf of Guinea in West Africa, was and is an area of gold deposits. This metal is both feared and worshipped. Well before the first contacts with Europeans in the fifteenth century, the Akan people used gold dust as a medium of exchange. However, the concept of “gold weights” came from Western traders (Dutch, Portuguese, English, and French).

The first question to ask is: are the figures really weights? In describing these figures, the Baolé use several different terms: *Dja-yôbwê*, *sika-yôbwê*, *shin-dra-yôbwê*, *nsangan-yôbwê*, *ngwa-yôbwê*. Let us look at the meaning of each of them.

As we see, the term “weights” appears nowhere in these descriptions.

The *dja* or *sanaa* was originally a package made of animal skin or thick cloth in which the Akan placed their figurines and certain accessories. It seems to have been a kind of encyclopedia written in miniature figures. The package and its contents symbolized the economic power of the living king and the spirits of the dead sovereigns. The act of taking possession of the *dja* signified for a new ruler that he was assuming the power to raise taxes, impose fines, and take measures to increase the state treasury. For his subjects, knowing that the ruler was in possession of the *dja* of the state meant that they judged him capable of administering the financial and economic heritage of the country.

Many different objects can be found in a *dja*, but we will mention here only the essential, original ones.

The equipment is a group of accessories used to manipulate the gold power. They consist of (1) balance scales, used to determine the weight value of different quantities of gold dust used as a medium of exchange; (2) spoons to put the gold

**Weights and Measures in
Africa: Akan Gold
Weights, Fig. 1** Weights
with figurative elements

dust on the plates of the scales; (3) boxes of many different kinds, their covers often decorated with graphic designs. They are used to hold gold dust already weighed or about to be weighed; (4) winnowing baskets used to separate and rid the gold powder of any impurities; and (5) sieves to separate the different grains of gold dust.

The weights provide knowledge of the weight and monetary value of the quantity of gold powder placed in the plate of the scale. There are three kinds of weights – figurative weights, weights with graphic designs, and geometric weights (Figs. 1, 2, and 3). Gold weights were (usually) made of an original alloy whose composition was similar to that of bronze and brass. However, there are also weights made of silver, copper, and solid gold.

The weights were made by the Tounfouê, an artisans' group, different from blacksmiths and jewelers. These artisans used the lost wax method to produce the weights.

The Akan used a system of computing weight consisting of 11 units. It began at *dama* and ended with *bèna*. It was possible to multiply *bèna* by infinity and the values went from single to double or were multiplied by two. There were three series of weights – small, medium, and large. They could be added and multiplied.

The small weights series consisted of ten monetary units and was used for all sorts of small transactions:

- ba = unit = 0.148 g
- ba (*gnon*) = ba × 2
- ba (*nsan*) = ba × 3
- ba (*nan*) = ba × 4
- ba (*nou*) = ba × 5
- ba (*nzien*) = ba × 6
- ba (*nzo*) = ba × 7
- ba (*motchué*) = ba × 8
- ba (*brou*) = ba × 10

**Weights and Measures in
Africa: Akan Gold**

Weights, Fig. 2 Weights
with graphic designs
(Photographs by the author.
Used with his permission)

**Weights and Measures in
Africa: Akan Gold**

Weights, Fig. 3 Weights
with geometric elements

The medium weights series consisted of seven units. The computation is done from simple to double, and each unit has multiples and submultiples.

Assan = 4 m.v.

Gbangbandia = 4 m.v.

Tya = 5 m.v.

Anui = 5 m.v.

Gua = 5 m.v.

Anan = 5 m.v.

Tyasue = 5 m.v.

Total = 33 m.v.

These 7 units comprise 33 monetary values. The smallest value is *météba* which equals 12 *ba* or 1.77 g. The largest value is the *ta*, which equals 348 *ba* or 51 g of gold.

In practice, the system worked as follows. For example, the *gua*, the fifth unit, comprised the following five monetary values:

Météba = 12 *ba* = 1.77 g of gold

Adjratchui = 24 *ba* = 3.55 g of gold

Tra = 48 *ba* = 7.54 g of gold

These are all sub-multiples of *gua*.

Gua = 96 *ba* = 14.20 g of gold (Unit of this series)

Guagnan = 192 *ba* = 28.40 g of gold (Multiple of *gua*)

The large weight and monetary values series had only three units. They were:

Banda = 384 *ba* = 56.80 g of gold

Banna = 432 *ba* = 67.44 g of gold

Pereguan = 478 *ba* = 71.92 g of gold.

In considering the weights and numeric representation, we will consider here only those weights with graphic signs which correspond with calculation and mathematics.

Concerning the signs and marks, the anthropologist François H. Abel has written: "A. Amélékia, a well known man named Diénélou confirmed for me that the Ancients

knew how to read from the weights. . . In the village of Lomo-north, in the region of Toumodi, the village chief knew that the signs on the weights had meaning."

Savary, the Director of the Department of Black Africa in the Museum of Ethnography in Geneva has written: "Each weight is the product of two signs written on it. . . Reading it is sometimes simple, but often difficult. This is because some Black Africans had a different concept for numeric figuration and for the representation of the product of two numbers. [Also] zero did not exist. . .". In the system, figures and numbers are represented by vertical and horizontal lines, such as marks and arrows similar to those still seen in charcoal in the houses of African villages.

Commenting in 1605 on the Akan system of accounting and calculating, the Dutch explorer and historian Pieter de Marées made this remark: "The Negroes have weights of copper and tin which they have cast themselves, and, although they do not divide in the same way we do, it comes out the same, and the accounting is always correct."

For the people of the Akan civilization, the gold weights contained in the *dja* constitute a fundamental cultural text, comparable to the Christian *Bible*, the Islamic *Qu'rān*, or the Hindu *Veda*. It is within this sacred package that they had consigned, in idiogrammatic letters and signs, their knowledge and values to be passed on to posterity. In this way, their descendants would not have to reinvent that which had been known by their ancestors and which constituted the foundation of their civilization.

Weights and Measures in China

Hans Ulrich Vogel

Metrology means the “science of weights and measures.” But when referring to premodern periods the term “knowledge of weights and measures” is more appropriate. In a more concrete sense, metrology is the art of calculation with number, weight, and measure units in the economic and fiscal domains as well as in science. “Metrosophy” may be defined as “number speculation within cosmological philosophemes,” but from a more inclusive perspective the relationships between magical, religious, and political thought on the one hand and metrology on the other also have to be taken into account. In both metrology and metrosophy, numbers are of great importance. In metrology, they are used for defining and counting measure and weight units, while in metrosophy they serve as basic stuff for the creation of systems of number symbolisms, magical numbers, and correlative numerologies.

For the study of metrosophy and metrology, two different types of sources are basically available. First, we may mention sources of the tradition type, like the metrosophical and metrological sections in chapters of the dynastic histories. Although these sections also contain information of a metrological nature, it is clear that they are principally metrosophical in character. The second important types of sources are concrete remains, especially the relatively great number of real ancient weights and measures which either have been excavated at archaeological sites or

which survived by having been handed down from generation to generation. While the sources of the tradition type are closely related with metrosophical thought and number systems, concrete remains inform us almost exclusively of metrological aspects and realities. The tension between these two clusters of information and data is of particular importance and is rewarding to be investigated.

Chapter 21A in the *Hanshu*, written in the first century AD, contains one of the first surviving texts that gives evidence of a system integrating metrology with such diverse fields as numerology, musical pitch, astronomical phenomena, astronomy, cosmology, historiography, and political, ethical, and moral thought. The textual arrangement of this chapter makes clear that metrology belonged to the traditional Chinese science of mathematical harmonics (*lü* or *lülü*).

Chapter 21A of the *Hanshu* states that harmonics consist of five categories: number, musical pitch, length measures, capacity measures, and weights and balances. All five had their origin in the *huangzhong* pitch-pipe, which had been created and standardized by the legendary Yellow Emperor. Obviously, the antiquity of these conceptual and technical devices was an important criterion for their purported eternal validity. Within the five categories a certain hierarchy is expressed, ranking numbers above, followed, in descending order, by pitch, length, capacity, and weight measures. Numbers are obviously of primary importance, because they provided the basic counting units for the other four categories. Metrology was grounded on a numerological system combining the numbers of the ► [Five Phases \(Wuxing\)](#) and other numerological concepts with the numbers derived from the changes of yin and yang as they are described in the *Yijing* (I Ching Book of Changes) and its commentaries. Moreover, weights and measures were conceived as an integrated system. With grains of medium-sized black millet, the length and capacity of the *huangzhong* pitch-pipe were measured and thus the basic length and capacity measure units derived. The weight of the grain filling of the pitch-pipe also served as the basis for fixing the weight units (Fig. 1).

Weights and Measures in China, Fig. 1 Handling the Wang Mang proto sliding callipers (From Dong-rui (1979) (in Chinese))

Concrete remains of ancient Chinese weights and measures are of great importance for supplementing the information contained in the largely normative written sources. A spectacular example are the proto sliding callipers of the Wang Mang period (AD 9–23), of which apparently three pairs survived.

The intaglio inscription on the movable part says: “Manufactured at the first day of the first month of the first year of the Shijian guo reign-period.” This corresponds to March 15, AD 9, the first day of Wang Mang’s interregnum. The front side of the fixed part of the sliding callipers is divided into 5 in. (*cun*), that of the movable part into 5 in. In addition, the 4 in. of the fixed part are further subdivided into ten parts (*fen*) each. With the Wang Mang proto sliding callipers outer diameters of less than 4 in. could be measured. The most conspicuous difference between modern sliding callipers and the Wang Mang piece is that the latter does not have the differential scale of the vernier.

No less spectacular is the great number of other Chinese metrological remains. For instance, more than 240 ancient length measures are known, which can serve as a basis for ascertaining the “true” length of a length measure unit of a given period. This is no easy task as may be shown in the case of the length measure unit *chi* of the Eastern Han period. Modern measuring has shown that the actual lengths of 85 concrete

chi measures of this period vary from 20.49 to 24.73 cm. Obviously, state efforts at unification and standardization of weights and measures were of limited success and collided with diverging interests having their origin in different regional, local, political, economic, fiscal, and social conditions. Small wonder that in the *Suishu*, the dynastic history of the Sui dynasty written in the early seventh century, 15 different *chi* measures are listed.

The development of the types of weighing apparatuses can be divided into three stages. From the fifth century BCE to the second century AD balances with equal arms prevailed. In the period from the third to the ninth centuries the steelyard with unequal arms appeared and was used together with the ancient balances. Finally, the third stage from the tenth to the early twentieth centuries was characterized by the emergence of the highly accurate *deng* steelyard and the introduction of a decimal system of weighing units. An important promoter in the introduction and improvement of the *deng* steelyard was the eunuch Liu Chenggui (950–1013). Liu was in charge of the court treasury and fiscal affairs. The purpose of the introduction of the *deng* steelyard was to reduce disputes in the weighing of precious metals, which arose between different officials involved in fiscal affairs.

Weights and Measures in Egypt

Ruth Hendricks Willard

The gradual change from a nomadic to a settled existence, which began about 8000 BCE, marked humankind's determination to shape the environment to their requirements. Needing units of measure for both building and agriculture, people

chose the most readily available and useable references – simple parts of the human body in various positions. The need for uniform measurements was recognized, and as early as 3000 BCE official reference standards of length, volume, and weight were being maintained in temples and royal palaces in Egypt, Mesopotamia, and around the eastern seaboard of the Mediterranean.

The standards developed in these ancient cultures moved westward, mostly as a result of trade, to the Greek and Roman empires, thence to Gaul and Britain via the Roman conquest. Egypt, by virtue of its geography a great trading nation and of its climate a preserver of archaeological treasures, has provided an incomparable record of this metrological heritage.

Measures of Length

Throughout the ancient Middle East, the basic unit of linear measure was the cubit, which was defined as the length of the forearm from the point of the elbow to extended fingertips. In Mesopotamia, the cubit was generally subdivided into 2 ft each of three or four palms, a palm having four digits. In Egypt, however, the most ubiquitous standard was the royal cubit. It was subdivided into seven palms (28 digits), these divisions having significant mystical relationship to the four 7-day phases of the 28-day lunar month by which time was reckoned. The basic sub-unit was the digit (finger width): 4 digits = a palm; 5 digits = a hand; 12 digits (outstretched forefinger tip to little finger tip) = a small span (1/3 cubit); 14 digits (outstretched thumb tip to little finger tip) = 1 large span (1/2 cubit). Measurements smaller than a cubit were expressed in digits (up to ten), in palms and digits, or rarely, as 1/2 or 1/3 cubit.

Surveys of the Great Pyramid confirm its construction according to the royal cubit of 20.62 in. (52.4 cm). The skill of the Egyptian workmen is shown by the fact that the sides of its base vary no more than 0.05 % from the mean length of 440 cubits (9,069.45 in. or 230,364 m). The Egyptians also employed a short cubit of

6 palms (24 digits) = 17.68 in. (44.9 cm) for general purposes including calibration of the Nilometers (masonry stairwells leading down to the river at points where the priests recorded the rise of the annual floods).

Egyptian measuring scales are square rods with one face half-beveled to form a reading surface. The fractions of the digit are shown by dividing the first into halves, the second into thirds, and so on down to sixteenths. The oldest extant cubit rods date from the Eighteenth Dynasty, 1550–1307 BCE; none are longer than the double cubit, 41.2 in. Most of those used by the workmen are made of wood with deeply cut notches of division. The stone cubit rods are generally ceremonial, belonging to the temples and crowded with inscriptions referring to the religious aspects of the digits as connected with the gods and with the signs of the nomes. On these, the calibrations are often carelessly marked.

Land was measured by a linear unit called *khet* or *khet u nu* (reel of cord) 100 royal cubits in length. Measuring cords were made of palm-fibre or flax-fibre and knotted at 5-cubit intervals. For long distances the foot (12 digits) and the pace (double step) were used; 2 paces measured heel to toe = the extended arms (4 cubits), and 100 paces = a stade. This distance later used by the Greeks in the Olympic foot races known as a stadium.

Measures of Area

The basic unit for reckoning areas of fields and nomes [a name given to regional divisions in Egypt] was the *setat*, the square of the *khet*, containing, therefore, 10,000 square cubits. Such an area was called a cubit of land, but was visualized as 100 parallel strips of land each 1×100 cubits. Ten *setats* were called a thousand of land. In devising ways to re-establish field boundaries after the annual flooding of the Nile, the Egyptians discovered the rudiments of geometry. A new unit formed from the diagonal of a square with sides equal to the royal cubit was found to be divisible by 40 digits of 0.73 in., twice the length

of the *remen* (forearm from elbow to clenched knuckles) and consequently named the double *remen*. Half of the area of 100×100 cubits was also called *remen* in land measure. By having two standards, one the diagonal on the square of the other, it was possible to denote areas in squares equal to one-half or double the area of others.

Measures of Time

Through studies based primarily on the movements of the heavenly bodies in relation to the regular flooding of the Nile the Egyptians established two calendars. The priests followed an exact year of $365 \frac{1}{4}$ days, while the civil year was subdivided into three seasons of 4 months each having 30 days – inundation, cultivation, and harvest – plus 5 days-upon-the-year.

Measures of Volume

In establishing standard units of capacity for barter, taxation, and medication convenient reference was made to human factors such as a mouthful (tablespoonful), handful, cupful (two handfuls) and sack- (hide-) ful for easy carriage. The principal Egyptian standards from small to large were the *ro*, *hin*, *hekat*, and *khar*.

Medications were prescribed in terms of the *ro* (mouthful, tablespoonful) = $\frac{1}{2}$ fl oz (14.5 cc). By the usual Egyptian method of doubling this standard produces 2 *ro* = 1 handful (fl oz, jigger); 4 *ro* = 2 handfuls (jack, jackpot); 8 *ro* = 4 handfuls (gill); 16 *ro* = 2 hands cuppedful (cup); 32 *ro* = jugful (pint, *hin*); 64 *ro* = pitcherful (quart) and, by extension, the old English measures including the gallon, peck, bushel, barrel, hogshead, and tun.

The *hin* for liquids was subdivided dimidially down to $\frac{1}{32}$ = 1 *ro*. There was also $\frac{1}{3}$ *hin* known as the *khay*, thirds being a peculiarity of Egyptian metrology occurring also in the subdivision of the cubit and *qedet* standards. There were two principal standards for larger volumes. Multiples of the *hin* were decimal: 10 *hin* = 1 *hekat* (4.7 L). The *hekat* was the official corn measure:

hekat = 10 hin; 30 hekats = 1 cu cubit. The khar, originally a hide or sackful, was a special standard = 20 hekats (94 L). Subdivisions of the hekat in the dimidial series $1/2$ – $1/64$ (=5 ro), an amount frequently prescribed for internal medications) were always written in symbols now known as the Horus-eye notation. The Rhind Mathematical Papyrus, attributed to the Twelfth Dynasty (1991–1783 BCE), provides the following conversion table: $9,600 \text{ ro} = 300 \text{ hin} = 30 \text{ hekat} = 3/2 \text{ khar} = 1 \text{ cubic cubit}$ (37 U.S. gallons).

The early use of additional capacity standards is documented by wall paintings in a Mastaba tomb of the Third Dynasty, ca. 2630 BCE. Two series of cylindrical capacity measures, one of copper, for measuring wine and oil, and one of hooped wood staves for grain, have been shown to conform to a mixed series in binary progression based on the standards of both the Egyptian hin and the Syro-Phoenician *kotyle* (21.4 cu in. or 350 cc). Other standards of volume used in Egypt include the Syro-Babylonian *log* (33.1 cu in. or 542 cc), the Attic *kotyle* (17.2 cu in. or 282 cc), and the Persian *kapetis* (74.9 cu in. or 1,227 cc).

Measures of Weight

A search for the origins of weighing reveals that this intuitive use of the lever evolved independently in at least three ancient civilizations – Mesopotamia, the Indus Valley, and Egypt – and that all three were routinely employing balance and weights by the middle of the third millennium BCE. The weights, made in durable stone, have survived in sufficient numbers to permit study of the ancient weight standards. However, very few balances, which were usually constructed of wood in the earliest periods, exist today.

It is possible, nonetheless, to trace not only the evolution of weighing instruments but also the uses to which they were put in dynastic Egypt during the period 2700–650 BCE. As a means of enhancing the quality of the afterlife of their leaders, Egyptian artisans carved or painted

scenes from their earthly life in tombs and temples. Because of a mild, dry climate, many of those monuments survived into modern times. While it is still possible for visitors to experience the excitement of discovering the weighing scenes in situ, not all of the tombs and temples have survived the two centuries of study and tourism to which they have been subjected. Colors have faded; walls and in fact entire structures have disintegrated or been destroyed or closed. We turn, therefore to the remarkable work of the Egyptologists of the nineteenth and early twentieth centuries, a period of intensive recording and copying of Egyptian inscriptions, reliefs, and paintings. Hence, it becomes necessary to consider not only possible errors in the original, but also the errors resulting from the deterioration of the works being copied.

For information regarding the practice of weighing, we are indebted primarily to Sir W. M. Flinders Petrie. He was the first Egyptologist to identify, collect, and study the ancient weights for the insights they could provide into the cultural and trade relations among the various nations of the Near East. His numerous publications include chapters on the metrological findings of each site excavated. Most large museums have specimens of ancient Egyptian weights.

The practice of weighing began with the discovery of metalworking. The earliest weights are of a small order, suggesting that at first only small quantities needed to be weighed. Egyptians developed two indigenous weight standards and as an international trading center employed at least six more. The Egyptian national standard was based on the qedet, which varied over time from 138 to 152 gr giving a median value of 144 gr (9.33 g). It was multiplied decimally: $10 \text{ qedet} = 1 \text{ deben}$; $10 \text{ deben} = 1 \text{ sep}$, as first recorded in a Third Dynasty tomb painting. The unit was sometimes divided into thirds as evidenced by a series of graves from the First Dynasty (2920–2770 BCE). The qedet is the basis of nearly all statements of weight from the Eighteenth Dynasty onward. The qedet and deben were also known as the kite and *uten* when applied to pieces of copper used as a medium of exchange.

Less well known but more influential in world affairs was the *beqa*, which was associated with the weighing of gold and silver from pre-Dynastic times and used in Egypt for nearly 4,000 years. Although the standard is seldom mentioned in Egyptian inscriptions, numerous beqa weights have survived. These are sometimes marked with the hieroglyph for gold (*nub*) perhaps recalling its origin in the Nubian gold fields. As in most Middle Eastern standards, the basic unit was called a *shekel*; 50 beqa shekels = 1 *mina*. The beqa shekel was multiplied decimally to 7,000 shekels and subdivided dimidially down to 1/16. Over time, the several distinct values merged into a single standard of 192 gr (12.4 g), which was adopted by the Greeks around 700 BCE as the standard of Aegina. From it evolved two of the Roman pounds, the silver denarius and the gold aureous coinage. In the seventh century AD it was adopted by the Arabic Empire for bulk gold and it ultimately became the basis for the English troy weight standard.

Other standards in use in Egypt included the Palestinian *peyem*, 120 gr (7.78 g); Mesopotamian *daric*, 129 gr (8.36 g); Attic *stater*, 135 gr (3.75 g); Persian *khairine*, 178 gr (11.53 g), and Phoenician *sela*, 218 gr (14.13 g).

The Evolution of the Equal Arm Balance

All of the balances used in Egypt before the Roman occupation in 30 BCE were equilateral, doubtless inspired by the yokes with which men balanced heavy loads on their shoulders. During the Old Kingdom (2686–2181 BCE) most balance beams were flat and rectangular, pierced vertically for support at the fulcrum and for the hangers, which were single cords hooked at the end to hold baskets or bags of gold dust. With but one exception, shown in (Fig. 1), they were made of perishable wood until about 1550 BCE. Hence, the only records of their design and use come from reliefs, paintings, and inscriptions.

Significant innovations during the Old Kingdom include specialized tongs to hold metal vessels, counterweights of a predetermined mass,

Weights and Measures in Egypt, Fig. 1 This is the earliest known Egyptian balance. It was skillfully cut from pinkish brown limestone, a material commonly used for making vessels in prehistoric times, but seldom later. The three suspension holes were drilled with a primitive bow drill and flint point. The beam is 3.35 in. long. Its width varies from 1.6 to 2.0 in. and its depth from 1.7 to 2.0 in. The diameter of the central hole is 0.03 in. and that of both end holes is 0.07 in. As to sensitivity, a change of 1 in 500 can be seen by the change of level. A plaster model of this balance was tested at the Science Museum in London (Photo at the Petrie Museum, University College, London by O. W. Willard in 1993)

tongues, and plummets to help in sighting the vertical. Nearly all of the Fifth and Sixth Dynasties weighing scenes come from the tombs of royal officials, and depict the weighing of metal in the course of manufacturing. There is no evidence of buying selling, or exchanging goods by weight in this early period.

The decline of the Old Kingdom was followed by the First Intermediate Period, an epoch of chaos, civil war, hunger, violence, and invasion. No evidence of weighing has been found from this period, which encompassed the 7th to 10th Dynasties and lasted from 2134 to 2040 BCE. Eventually Theban warlords gained supremacy

and established the Middle Kingdom with its capital first at Thebes and later at Itjtawy, a newly built city near Memphis.

The Middle Kingdom

Weighing scenes are found at Beni Hasan, the most noteworthy necropolis of the Middle Kingdom, where 39 tombs are cut out of the rock cliffs at Beni Hasan, on the east bank of the Nile. The tomb paintings here depict balances with an improved suspension system. The beam is suspended from a bracket near the top of the upright and can swing more freely because of a ring added to the top of the tongue. As in the fifth and sixth Dynasties, the plummet appears to hang from a point near the bottom of the tongue suggesting that the tongue and beam are rigidly attached and move together. The baskets are now suspended by multiple cords, depicted as two but presumed to be four, since that is also the case in the New Kingdom, from which we have extant pans with four holes. One representation shows workers weighing two sets of objects against one another. Another representation shows the introduction of shallow, concave pans made possible by the multiple suspension cords. Weight boxes are shown below each standing balance.

A totally new aspect of weighing appears in one Twelfth Dynasty relief. Here we see a jeweler who has left the workplace to show his finished product to the nomarch (local ruler). Reading between the lines, we note that he has suspended the balance from a full-length stand, but by using an extension cord, he has brought the scale and its contents down to a level he can reach while kneeling before his ruler.

During the Second Intermediate Period, from 1640 to 1532 BCE, the political situation was unstable, with several dynasties ruling in various areas simultaneously. While there was undoubtedly turmoil during the takeover, Egyptian life was enriched by the introduction of horses, wheeled chariots, hump backed cattle, and new tools, weapons and musical instruments. Innovations relevant to metrology included the working of bronze and weights cast in the shapes of animals.

The New Kingdom 1550–1070

Both the equipment and the philosophy of weighing underwent major changes during the New Kingdom (1550–1070 BCE). While the equal arm balance of the Old and Middle Kingdoms had been modified in ways that made using it more convenient, there was still the problem of accuracy. The end suspension cords could wander in holes drilled vertically through the beam and those holes, even if exactly equidistant from the fulcrum initially, might not remain so after the wearing away inherent in use. Either early in the New Kingdom (or possibly late in the Second Intermediate) a radically different scale beam made its appearance. Constructed of either wood or bronze, it was round in section. Suspension cords entered at the beam end through longitudinal bores and emerged through intersecting radially drilled holes, being knotted on top of the beam. Any inequality in the distance of the beam ends from the fulcrum could be adjusted by simply filing the longer end, restoring the balance to accuracy. This principle was later improved upon in the large standing balances with flared beam ends that allowed the four strings to diverge from the lowest point on the flange, making for even greater accuracy.

While the great majority of representations from this period depict large, stately standing balances, the extant specimens are all small and portable. The beams, which may be of bronze or wood, are invariably round in section. The Cairo Museum displays several. A hand-held balance at the Science Museum in London was excavated at Amarna and dates from the reign of Akhenaten, Eighteenth Dynasty, c. 1331 BCE. The length of the round, tapering wooden beam is 30 cm and the diameter of the copper pans is 7.4 cm; the sensitivity is plus or minus 2 gr per hundred in each pan. Bronze animal weights characteristic of the Eighteenth Dynasty are shown with this balance. Two previously unpublished specimens were found at the University of California's Phoebe Apperson Hearst Museum of Anthropology. Both were excavated at Naga ed-Deir during the 1899–1904 Hearst Expedition led by G.A. Reisner. While it is impossible to date either

Weights and Measures in Egypt, Fig. 2 Two New Kingdom-type balance beams (Photo by O. W. Willard by permission of the Phoebe Apperson Hearst Museum of Anthropology, University of California)

one with certainty, both have the general characteristics of New Kingdom balances (see Fig. 2).

Specimen 6-13624, from a cemetery dating from the late Old Kingdom through the Middle Kingdom, was found near the entrance of tomb 434 with the excavator's notation *ghadim* (fill). The wood is acacia, sub-species not identified. The round, tapering beam is 50.3 cm long with a diameter of 2.7 cm at the center, drilled in the New Kingdom manner for central and end suspensions. Unlike the Amarna balance above, the beam has a definite arch in the middle. There is the imprint of a narrow saddle or support of some kind at the fulcrum. The ends are knobbed, with a decorative channel around each. On each side of the suspension holes, there is a decorative double annulet with a channel between. No pans were found.

Specimen 6-2702 is believed to have come from a cemetery dating from early dynastic to Roman times. The wood is acacia, sub-species not identified; the round beam is 31.2 cm long and 2.0 cm in diameter at the center. There is a bulge in the center of the beam and the ends are slightly flared, foretelling the more pronounced flanges of the large ceremonial balance. There is also an unexplained diametric hole about 1.0 cm from the fulcrum hole. No pans were found.

The most magnificent weighing scenes are those representing the brilliant Eighteenth Dynasty, which ruled Egypt from 1550 to 1307 BCE. The ceremonial balances, sometimes 10 ft tall, are often adorned with the head of a god as a finial. The beam hangs from a bracket that may be in the shape of the feather representing Maat, the goddess of truth. The bronze tongue, which has evolved into a pointer, moves with the beam. In many examples, the operator holds the plummet

in his hand as if to inspect it for flaws before beginning the weighing procedure. Shallow concave pans, usually of metal, are suspended by multiple cords thought to be four in number although sometimes depicted as two or three. The conventional stone weights, geometric in form, have been replaced with handsome animal shapes in cast bronze.

Ambiguities in the drawings coupled with the lack of physical specimens have fostered intense interest in the central suspension and indicator system. The explanation most generally accepted was offered by Petrie in 1888:

The beam was suspended by a loop or ring from a bracket projecting from the stand; this bracket is shown in side view though at right angles to the beam just as the Egyptians drew a full eye in a side face. Then below the beam, a long tongue was attached, not above the beam, as with us. To test the level of the beam, a plummet hung down from the tongue, and it was this plummet which was observed to see if the tongue was vertical and the beam horizontal. The weigher is often shown steadying this plummet with his hand, as it would be set swinging by the motions of the beam. Such is the whole system, which is so simple that it seems strange that any mistake could be made about it to say nothing about the mechanical absurdity of the explanation which has been current for so long.

The "mechanical absurdity" theory to which Petrie referred had been offered by Wilkinson in 1837. Referring specifically to an illustration showing the balance being used by the *Qabbaneh*, or Public Weighers, he wrote,

The beam passed through a ring suspended from a horizontal rod immediately above and parallel to it, and when equally balanced, the ring, which was large enough to allow the beam to play freely, showed when the scales were equally poised. It had the additional effect of preventing the beam

tilting when the goods were taken out of one, and the weights allowed to remain in the other. To the lower part of the ring a small plummet was fixed and this being touched by hand and found to hang freely indicated, without the necessity of looking at the beam, that the weight as just.

Though acclaimed for his understanding of the Egyptian artistic canon and for the accuracy of his copies, Wilkinson overlooked the obvious fact that the vertical plane of the bracket, shown in profile, would have been perpendicular to that of the beam. The single-ring hanging mechanism as shown could not possibly have worked. It would appear that either the original drawing was erroneous, or deterioration in the ancient surface caused Wilkinson to miscopy it.

Recent research has centered in the nature and function of the triangular shape bisected by the plumb line that project below the beam. Spiegler postulates an arrangement of three strings fastened at the beam and equipped at the tip with a plummet. As the beam is tipped, a slack string allows the plummet to swing. Jenemann and Robens note that such a mechanism would work only with large deflections that could be seen more easily by visual observation. Furthermore, in colored drawings the triangle is clearly opaque, indicting a solid object. They then suggest that the flat side of the triangular plane, while shown frontally in the drawings, is actually perpendicular to the beam, while the plummet hangs independently in front of the tongue, an arrangement considered to be more sensitive than one in which the tongue pierces the beam longitudinally.

Skinner states, "For larger wooden or bronze beams a bronze tongue was driven vertically through the center of the beam with a ring on top for suspension from a bracket. The tongue protruding below the beam acted as a swinging index, which was sighted against a freely-suspended plum-bob to denote when the beam was horizontal and in balance." In the absence of New Kingdom specimens, perhaps conclusions can be drawn from a small bronze goldsmith's balance dating to the Greco-Egyptian period, 304–30 BCE. The beam is suspended from a ring in the bracket intersecting a ring in the top of the tongue or pointer, which pierces the

beam and extends below it. The plummet hangs from the bracket, behind the tongue. The original is in the Cairo Museum and its replica, a plaster cast, is in the Science Museum, London.

Expanding Roles for the Balance: Trade, Tribute, Offerings

With Egypt's transformation to an international power, new roles evolved for the balance. Along with the customary depictions of jewelers and other metal workers there are scenes of the balance used in weighing tribute to the pharaoh and offerings to the national god Amun and, for the first time, in domestic and foreign trade. Short gold or silver cylinders about 5 in. in diameter served as a sort of currency. Variable in mass, these must have been weighed in each transaction. Medicine however, continued to be measured rather than weighed.

The earliest known depiction of the balance in commerce is found in a remarkable painting from the tomb of Kenamun, Mayor of Thebes and Superintendent of the Granaries of Amun under Amenophis III, 1391–1353 BCE. Syrian ships were anchored on the Nile off Thebes, while on shore two male shopkeepers engage in private trading with the sailors. Since the commodities – sandals, apparel, and various objects – are too large to weigh on the hand balances shown, the sellers are obviously weighing out the amount of gold needed to make the purchases.

Among the various public officials were the Qabbaneh, or public weighers, who erected their balances in the market place while a notary stood by to record the details. They were required by law to adjust the sale of each commodity with the strictest regard to justice, without favoring either the buyer or the seller. The penalty for falsification of weights or records was the loss of both hands, inflicted upon the seller, the weigher, and the notary alike. The Qabbaneh were still functioning in early twentieth century Thebes.

Hatshepsut, who ruled as Egypt's only female Pharaoh (1473–1458 BCE) built at Deir el Bahari a magnificent temple with extensive terraced

gardens facing the Nile. She dispatched an expedition to the fabled land of Punt in search of treasures to be offered to the sun god Amun, to whom the temple was dedicated, and recorded the presentation in a monumental relief on the south face of the second terrace. In the weighing scene, a massive balance is piled high with cylindrical gold ingots being weighed against some loaf-shaped weights of the Middle Kingdom and some bronze animal-shaped weights characteristic of the Eighteenth Dynasty. In the background are trays holding additional loaf shaped weights and quantities of electrum (a naturally-occurring alloy of gold and silver) in bars and rings. The inscriptions read,

The balances accurate and true of Thoth, which the King of Upper and Lower Egypt (Hatshepsut) made for her father Amun, lord of Thebes, in order to weigh the silver, gold, lapis lazuli, malachite, and every splendid costly stone, for the sake of the life, prosperity, and health of her majesty. Weighing the gold and electrum, the impost of the southern countries, for Amun-Re, lord of Thebes. Recording in writing, reckoning the numbers, summing up in millions, hundred of thousands, tens of thousands, thousands, and hundreds.

Thutmose III, successor to Hatshepsut, so extended the Egyptian holdings in Asia and northern Ethiopia that he has been referred to as the Napoleon of Egypt. During this period, the coffers of the state were greatly enriched by both tribute from and trade with the nations they had subdued. A weighing scene in the tomb of his Vizier, Rekhmire, is inscribed in part, "This great heap of electrum, which is measured by the heket, making 36,692 deben.

The Papyrus Harris, now in the British Museum, represents the testimony of Rameses III, Pharaoh (1194–1163 BCE) as he nears the end of his life and affords an understanding of both the physical nature and the significant role of the ceremonial balance in the New Kingdom. Describing his stewardship as the god's representative, he states as part of the prayer and recital of the king's benefactions,

I made for thee splendid balances of electrum, the like which had not been made since the time of the god. Thoth sat upon it as guardian of the balances, being a great and august ape of gold in beaten work.

Thou weighest before thee, O my father Re, when thou measurest of gold and silver by the hundred thousands, brought as tribute before thee from their coffers, and given to thy august treasury in the house of Atum. I founded for it (namely the balance; evidently offerings were made to it) daily divine offerings in order to supply its altar at early morning.

In another section, Rameses describes the king's gifts to Re including (in part), "Fine mountain gold and gold for the balances 1,278 deben, 9 $\frac{2}{3}$ kedet. (The gold amounts to some 311 $\frac{3}{4}$ pounds troy, and the silver to nearly 461 pounds troy.) Crude silver for the balances and silver in vessels 1,891 deben, $\frac{1}{2}$ kedet. Black copper for the balances 67 deben, 3 kedet.

Weighing the Soul

Souls too were weighed. The Egyptian concept of right conduct as a prerequisite for admission to paradise grew out of the cult of the god Osiris, which with its promise of immortality began to flourish during the First Intermediate Period. But it was first represented pictorially in the New Kingdom, when an elaborately illustrated roll of papyrus known as the Book of the Dead (or, more properly, The Book of Coming Out by Day) was placed in the tomb. Along with spells and instructions for entering into the kingdom of the gods, each Book of the Dead included a weighing scene in which the heart of the deceased, often represented by the hieroglyph for heart, was weighed against the feather of truth, symbol of the goddess Maat. The deceased was required to make a "negative confession" denying the commission of 42 specific sins such as giving short measure or falsifying the scales of the balance. The jackal-headed god Anubis tested the plummet of the scales, while the ibis-headed god Thoth prepared to record the results and a beast called the Devourer of Souls stood by to perform his duty, should the applicant's heart be found wanting (see Fig. 3).

This allegorical concept, first presented graphically by the Egyptians, persisted in the Christian world through the Middle Ages as demonstrated by surviving legends, stained glass windows, and

Weights and Measures in Egypt, Fig. 3 The Judgment Scene: Ani's heart being weighed in the balance (the first three of six panels). *Left to right, top:* The company of the gods, who hear Ani's testimony. Lower register, *left to right:* Ani and his wife Thuthu entering the Hall of Judgment; Rehenet and Meskhnet, the Goddesses of birth; (small figures. L 2 r) Ani's soul, Ani's Embryo, Ani's luck or destiny; Anubis testing the tongue of the balance;

Thoth recording the result of the weighing, The Devourer of the Unjustified; Not shown here: Horus, the falcon-headed god, introducing Ani into the presence of Osiris; Ani kneeling before Osiris, Osiris enthroned within a shrine. Behind him are Isis and Nephthys, and before him upon a lotus stand, the children of Horus (Wallis, 1969). The original Papyrus of Ani is in (The British Museum, No. 10470 Sheet 3 and 4)

paintings in which Anubis is replaced by St. Michael and the feather replaced by a toad. In 1901, Dr. Duncan McDougal of Haverhill, Massachusetts conducted the first of several experiments to determine whether the soul has weight. He found that in addition to the gradual weight loss related to the loss of body fluids as death approached, at the exact moment of death there were sudden weight losses of $\frac{3}{8}$ oz, $\frac{1}{2}$ oz, and $\frac{3}{4}$ oz. He attributed this weight loss to the departure of the soul. In his book, *Weighing the Soul*, Fisher relates other scientific research dating from Leonardo da Vinci in 1515 to American and European physicists in modern times. As recently as 1972, according to Agence France Press, a Swedish doctor set out to determine the mass of the human soul by placing the deathbeds of seriously ill patients on extremely sensitive scales. As each died and the soul left the body, the needle dropped 21 g, he reported.

The reliefs and paintings with which the Egyptians adorned tombs and temples celebrate the enduring values of their culture over a period of more than 3,000 years. The Eighteenth Dynasty

weighing scenes with their monumental balances and graceful animal-shaped weights are generally considered the apex of the genre. After this period of artistic and religious ferment Egypt returned to the old familiar ways, recasting their weights in geometric shapes. And as time went on, the illustrations grew more and more fanciful, as if the artists preparing them were not familiar with the actual instruments. While these enigmatic drawings, at once lively and serene, do not reveal all the technicalities of the Egyptian balance, they do provide a window into an ancient culture whose achievements in many fields are still reflected in modern life.

Whether constructed of wood or of bronze, the improved Egyptian balance became the standard weighing instrument of the Near East until Roman times. Glassmaking, another technical innovation of the Eighteenth Dynasty, was applied to metrology with the production of a few weights during the Roman and Byzantine periods. The Arabs, after their conquest of the country in AD 640, continued the tradition, issuing a fine series of reference weights for their

coinage. These are circular discs of transparent glass in various colors molded with a thick rim surrounding a central depression and civil inscriptions in Arabic. The Arabic standard of metrology continued to be dominant through the nineteenth century with standards varying city by city and by commodity. The metric system was made permissible in Egypt in 1873.

Weights and Measures in Islam

Ulrich Rebstock

In the sphere of Islamic influence the Quranic injunction “to give full measure and to weigh with the right scales” (*Qur’ān* 17:35), led – in the long run – to systems of measuring that were subjected to the authority and control of politics and law. But only a few measuring standards were substituted by new Islamic prescriptions. The most lasting novelty set off through the Quranic revelation affected the measure of time. It assumed a dual character. The natural solar year gave way to the ritual lunar year (29–30 days of the month), except in some fields of public administration and astronomical science. Within the sphere of the metrological systems of measures and weights, however, the *Qur’ān* remains vague. Among the terms most often mentioned, *kayl* or *mikyāl* (Sura 12:12 and

passim, ‘measure of capacity’), *mīzān* and *mithqāl* (Sura 6:152, 21:47 and *passim*, ‘weight’), range first. Others, like *qinṭār* (3:75, ‘hundred-weight’), *darāhim* (3:75, pl. of *dirham*), *dīnār* (3:75) and *ḥabba min ḥardal* (21:47, ‘grain of mustard’), are used in a metaphorical sense. A more systematic elaboration of metrical definitions and ratios, mainly for juridical purposes, was effectuated in the ‘traditions of the Prophet’ (*ḥadīth*, pl. *aḥādīth*). The characteristic aspects of the genesis of Islamic law – a cumulative development until the fourth and tenth century, geographically restricted proliferation of the various law schools (*madhāhib*), lack of normative authority – did, however, not allow for the introduction of uniform and ubiquitously accepted Islamic metric systems. Thus, the weights and measures which were used in Arabia and outside it, in the lands conquered by the Muslims, co-existed side by side, replaced each other, sometimes only by function, or by name, or intermingled. The striking feature of the metric systems that were in use in the early, medieval and pre-modern Islamic countries was their diversity. Neither in time, nor in space, could standard values develop that were accepted beyond their regional borders and their rulers’ period. Although some names of units of measure, e.g. *dhirāʾ*, *dirham* or *raṭl*, were widely diffused throughout the Islamic world, their absolute values and use in practice differed considerably. Notwithstanding this bewildering array of measures, a few basic terms that have survived until modern times stand for the cultural continuity between the Ancient Orient and the Islamic world: *raṭl* (Greek litron, ‘litre’), *irdabb* (Greek artabe, Persian ‘measure of capacity’), *maṭar* (Greek metretes, ‘measure of 40 L’), *ḳisṭ* (Greek xestes, Latin sextarius, ‘jug’), *qinṭār* (Latin centenarius, ‘hundredweight’), *ḳaf īz* (Persian ‘measuring cup’), *ḳīrāṭ* (Greek keratios, ‘carat’), *istār* (Greek stater, ‘weight of gold coin’), *dirham* (Greek drachme), *dīnār* (Latin denarius), *kayl* (Aramaic measure of capacity), *mann/mannā* (Babylonian unit of weight), *kurr* (Babylonian measure of capacity).

The development of systems of measure was influenced by the interplay between cultural

tradition and the order of authorities. Until the tenth century, the spread of Islam brought about an intercontinental economic and cultural sphere which amalgamated measuring standards of Egyptian, Arabic, Greek, Roman-Byzantine, Mesopotamian and Persian origin. This resulted in a multiplicity of regional and functional systems of measurement, which were constantly modified by power politics, institutional reforms or, simply, by the rulers’ autocratic order. Quite often, the advent of new dynasties brought about the introduction of new metrological standards, mainly in the field of the basic weight units of currency of gold (*mithqāl*) and silver (*dirham*), and the exchange rate of gold *dīnār* and silver *dirham*, which were fixed at a very early state by the canonical texts of the *Qurʾān* and the prophetic tradition (*ḥadīth*). Contrary to the more or less stable weight rate (10 weight *dirhams* equal 7 weight *mithqāl*), which everyday use polished into the handier ratio of 3:2, the prescribed rate of value (10 silver *dirhams* equal 1 gold *dīnār*) incessantly deteriorated over the course of time. Ratios of 12:1, 16 4/5:1, 20:1, 30:1 and even 50:1 are recorded. Nevertheless, modern Islamic jurists insist on referring to the canonical rates (10:7; 10:1) when, for example, fixing the minimum income (*niṣāb*) for the obligatory alms payment (*zakāt*) by Muslims of a determinate portion of their lawful property. The canonical ratio of the value of gold and silver (10:1) reflected the historical situation in the Mediterranean region and the Middle East after the Roman period (12:1). During the Il-Khānid period (thirteenth to fourteenth century), silver from Central Asia was massively imported to the West, the price of silver sank again, for a short period, to the Roman value. Gold, in contrast, remained remarkably stable over the millennium. Under the Persian king Darius the Great (522–486), mutton cost the same as in Anatolia in 1340: the equivalent of 1.9355 g pure gold.

Alphabetic list of abbreviations used

<i>ar</i>	<i>aruzza</i> , pl. <i>aruzzāt</i>	Grain of rice
<i>ash</i>	<i>ashl</i> , pl. <i>ashwāl</i> , <i>ushūl</i>	Part of a ‘rope’
<i>az</i>	<i>azla/azāla</i> , pl. <i>azāla</i> , <i>azālāt</i>	Unit of capacity measure

(continued)

<i>as</i>	‘ashīr, pl. ‘ashīrāt, ‘ushrān, a‘shur	Tenth
<i>ba</i>	baṭṭa	Leather bottle
<i>bā</i>	bāb, pl. abwāb	Portion
<i>bā‘</i>	bā‘, pl. abwā‘	Arms’ span
<i>da</i>	dāniḳ, pl. dawāniḳ, dawānīḳ	1/6 of a dirham/dīnār
<i>dh</i>	dhirā‘, pl. dhirā‘āt, adhru‘	Ell
<i>dī</i>	dīnār, pl. danānīr	Gold dīnār
<i>dir</i>	dirham, pl. darāhim	Silver-dirham
<i>dj</i>	djarīb, pl. djirbān, adjriba	Unit of square measure
<i>djo</i>	djou	Barleycorn (Persian)
<i>fa</i>	fals, pl. fulūs, afluṣ	Small coin
<i>fad</i>	faddān, pl. fadādīn	Yoke of oxen
<i>far</i>	farq	Unit of capacity measure
<i>fā</i>	fātil	Small unit of weight
<i>ghi</i>	ghirāra, pl. gharā’ir	Sack
<i>ha</i>	habba, pl. hubūb, habbāt	Seed
<i>hab</i>	habl, pl. hibāl, hubūl	Rope, thread
<i>hi</i>	himl, pl. aḥmāl	Camel-load
<i>ir</i>	irdabb, pl. arādibb	Unit of capacity measure
<i>is</i>	istār, pl. asātir	Unit of weight measure (Greek)
<i>iṣ</i>	iṣba‘, pl. aṣābi‘	Width of middle finger
<i>ka</i>	kaff, pl. kaffāt	Hand
<i>kā</i>	kāra	Load carried on the back
<i>kay</i>	kayl/kayla, pl. akyāl, akāyil	Unit of weight measure
<i>kayl</i>	kayladja, pl. kayladjāt, kayālidj	Unit of capacity measure
<i>ku</i>	kurr, pl. akrār	Unit of capacity measure
<i>ka</i>	kaḟīz, pl. aḳfīza, kifzān	Unit of capacity weight
<i>kab</i>	kab(a)ḍa, pl. kabaḍāt	Width of fist
<i>kad</i>	kadaḥ, pl. aḳdāḥ	Unit of capacity measure
<i>kal</i>	kalam, pl. aḳlām	‘Strip’
<i>kām</i>	kāma	Build, fathom
<i>kaṣ</i>	kaṣaba, pl. kaṣabāt	Pole, rod
<i>kin</i>	kinṭār, pl. kanāḟīr	‘Hundredweight’
<i>kis</i>	kisṭ, pl. aḳsāt	‘Portion’
<i>kī</i>	kīrāt, pl. qarārīt	Carat
<i>ku</i>	kulla, pl. ḳulal, ḳilāl	Jug

(continued)

<i>ma</i>	mann/mannā, pl. amnān, amunnā’	Unit of weight measure
<i>mak</i>	makkūk, pl. makākīk	Unit of capacity measure
<i>mar</i>	marzbān	Unit of capacity measure (Persian)
<i>maṭ</i>	maṭar, pl. amṭār	Unit of liquid
<i>mi</i>	mithkāl, pl. mathāḳīl	Unit of weight measure
<i>mish</i>	mishkā‘	Drinking-vessel
<i>mu</i>	mudd, pl. amdād	Unit of capacity measure
<i>mud</i>	mudy, pl. amdā’	Unit of capacity measure
<i>na</i>	naḳīr	‘Small spot’ (Arabic)
<i>nu</i>	nügi, pl. nügiler	Unit of weight measure (Turkish)
<i>oḳ</i>	oḳka, pl. oḳkalar	Unit of weight measure (Turkish)
<i>pe</i>	peymāne	Bowl
<i>r</i>	raṭl, pl. arṭāl	‘Litre’
<i>ru</i>	rub‘, pl. arbā‘	Fourth
<i>sha</i>	sha‘īr, pl. sha‘īrāt	Grain of barley
<i>shi</i>	shibr, pl. ashbār	Span of hand
<i>si</i>	silsila, pl. salāsīl	Chain
<i>su</i>	sunbul, pl. sanābil	Ear of grain
<i>ša</i>	šā‘, pl. aṣwu‘, aṣwā‘	Unit of capacity of weight
<i>th</i>	thumn, pl. athmān	Eighth
<i>ti</i>	tillīs	Unit of capacity measure
<i>ṭa</i>	ṭassūdī, pl. ṭasāsīdj	Unit of weight measure
<i>‘ush</i>	‘ushr, pl. a‘shār	Tenth
<i>ūk</i>	ūkīya, pl. awḳiyā, ūkīyāt	Unit of weight measure
<i>wa</i>	waiba	Unit of (dry) capacity measure
<i>was</i>	wasḳ, pl. awsāḳ	(Camel’s) load
<i>za</i>	zabīl	Basket made of palm- leaves

The overall cultural diversity of the Islamic world corresponds to the diversity of the metric systems, which came into use between the Atlantic and the Indian sub-continent. Three geographical units can be differentiated: The Islamic Arab West, from Andalusia to Iraq, Persia and the adjacent areas under Persian influence, and India. The following comments omit the metric systems of India (see *EI* ² VI, pp. 121a–122a, s.v. *makāyīl*,

and VII, pp. 138a–140b, s.v. *misāḥa*) and concentrate on the development in the Arab West, in consideration of the situation in Persia. Emphasis is laid on the early Islamic and medieval period. The absolute equivalents in modern metric values stem back to archaeological evidence or observations of European travellers.

Measures of Length

Along with the basic unit of length, the *dhirāʿ*, several other units were used, some of them only for particular purposes (construction, geometry, etc.). In theory, i.e. without considering their actual common occurrence or precise values, these units could be arranged to the following equation:

$$1 \text{ ash} = 1 \text{ si} = 10 \text{ bā} = 10 \text{ kaṣ} = 15 \text{ bā} \cdot (\text{or } \text{kām}) = 60 \text{ dh} (= \text{Persian } \text{gaz}) = 360 \text{ kab} = 1,440 \text{ iṣ} = 3,600 \text{ fa} = 8,640 \text{ sha}.$$

The ‘black ell’ (*al-dhirāʿ al-sawdāʿ*), being ca. 54.04 cm, is said to refer to the length of the ell (from the elbow to the tip of the middle finger) of a slave of the Caliph al-Manṣūr (r. 754–775) or the Caliph al-Maʾmūn (r. 813–833). Another etymology links the measure to the unit by which the ‘Nilometer’ of the island of al-Rawḍa was operated. There are almost 30 variants of the ell, some varying 30-fold from the original. By the eleventh century, at least 11 different types of *dhirāʿ* can be differentiated:

- 1 *dhirāʿ sawdāʿ* = $1 + 1/7 + 2/3 \cdot 1/7 \text{ dh al-yad}$ (of the hand) = $1 + 1/8 + 1/9 \text{ dh al-ḥadīd}$ (iron ell)
- 1 *dh fiḍḍīya* (silver) = $1 - 1/7 \text{ dh al-sawdāʿ}$
- 1 *dh yūsuf īya* (of Abū Yūsuf, d. 798) = $1 - 2/3 \cdot 1/7 \text{ dh al-sawdāʿ}$
- 1 *dh hāshimīya* (of the Banū Hāshim) = $1 + 1/8 + 1/10 \text{ dh al-sawdāʿ}$
- 1 *dh bilālīya* (of Bilāl b. Abī Burda, d. 739) = $1 \text{ dh al-sawdāʿ} + 2 + 2/3 \cdot 1/7 \text{ iṣ}$
- 1 *dh fiḍḍīya* (al-misāḥa) = 7 or 8 *dh al-yad*
- 1 *dh ʿumarīya* (of ʿUmar b. ʿAbd al-ʿazīz, d. 720) = $1 + 1/2 \text{ dh al-yad}$

- 1 *dh mīzānīya* (surveyor’s ell) = 3 *dh al-yad*
- 1 *dh mābahrāmī* = $1 + 1/2 \text{ dh al-ḥadīd}$

In addition to these different norms of the *dhirāʿ*, a multitude of ells was used depending on the profession involved: carpenters, cloth-makers, constructors etc. Moreover, the ells used in different cities under the same name differed: the medieval cloth-ell of Damascus (ca. 63.035 cm), for example, was 1/12 longer than the cloth-ell of Cairo (58.187 cm).

Measures of Area

The calculation of the surface of (straight) areas operated with the conventional measures of length. The basic units, however, were the *kaf īz* and the *djarīb*, two specific measures of surface area. Originally and throughout the Islamic period, both units also served as measures of capacity. One *djarīb* was conceived of as representing the surface area of agricultural land which could be sown with the amount of seed one *djarīb* contained.

Based on the ratio of the length units ($1 \text{ ash} = 10 \text{ bā} = 60 \text{ dh} = 360 \text{ kab} = 1440 \text{ iṣ}$), the following ratio of units of surface area measurement can be generated:

$$1 \text{ ash} = 60 \text{ dh} \cdot 60 \text{ dh} = 3,600 \text{ dh}^2 = 1 \text{ dj}$$

and:

$$1 \text{ dj} = 10 \text{ ka} = 10 \cdot 360 \text{ dh}^2 \\ = [\text{in Persia}] 60 \text{ ka} = 600 \text{ ʿas} = 600 \cdot 6 \text{ dh}^2 \\ = 100 \text{ ʿas} = 100 \cdot 36 \text{ dh}^2$$

This *djarīb* was called the ‘small’ *djarīb*, being 100 square *kabaḍa* (or *kaṣaba*; the units being often exchangeable) which renders: $100 \cdot (399 \cdot 399 \text{ cm})^2 = 1,592 \text{ m}^2$. The ‘big’ *djarīb* had $5,837 \frac{1}{3} \text{ m}^2$, i.e. $3 \frac{2}{3}$ ‘small’ *djarīb*, and corresponded roughly to the predominantly Egyptian *faddān* which was calculated as 400 square *kaṣaba*, i.e. $6,368 \text{ m}^2$. During the nineteenth century, the *faddān* was reduced to $4,200.833 \text{ m}^2$.

Dirham	6			48 <i>baghdādī/baṣrī</i> 36 <i>ḥurās./shāmī</i>	60	96	
III. Dīnār	[12]	[20]	24	60			240
IV. Dīnār		24/20	576	[72] 600/7		600	
V. Dīnār	6			75	60		

If multiplied with one another these units render the matrix (see above).

There is substantial evidence that the professional surveyors during the Abbasid period used a specific system of calculation. They divided the biggest unit, the *azla*, into 100 *dh mīzānīya* which corresponded to 48 *iṣ ʿumarīya* (see above), hence:

$$1 \text{ az} = 100 \text{ dh}^2 = 100 \cdot 12^2 \text{ ḳab}^2 = 100 \cdot 12^2 \cdot 4^2 \text{ iṣ}^2$$

In the Turkish lands of the Ottoman Empire (Minor Asia, Iraq, Syria and Palestine) the *dönüm* (turn), Arabic *dūnam*, was – until recent times – the standard measure of area. Originally measuring 939 m², it has been adjusted in colonial times to 1,000 m² (in Iraq to 2,500 m²) (Tables 1, 2, and 3).

Measures of Capacity

Most of the confusion about the system of the Islamic measures of capacity, both in primary medieval and in modern secondary texts, dates back to the Oriental practice to measure grain, pulse, and some liquids in capacity, but not in weight. The Arabic term *mīzān* does not clearly differentiate between the two. The transition from volume to weight needs the related quantity of the litre of water: the volume of approx. 75–77 kg of wheat and 60–72 kg of barley correspond to the volume of 100 kg/L of water.

From this economic and agricultural use of measures of capacity the proper mathematical and technical calculation of volumes must be set apart. This calculation is built on the calculation

of the surface area multiplied by the third dimension. The names used for the cubic units of measure do not change. Related to the *dhirā·mīzānīya* and based on the ratio $1\ az = 100\ dh^3 = 100\ ku$, the following values are produced: (see matrix below).

Most of the units of measures of capacity are regarded as units of weights too. It is therefore impossible to separate the two systems properly. Depending on the material measured, additionally different types of the same unit, e.g., a 'honey-*farḳ*' or a 'barley-*irdabb*', were used. The absolute values of these types differed considerably in different regions and periods. In order to allow a comparative overview, units that are related to each other by practical use are grouped together. Minor local variations and temporal changes are ignored.

Few of these units have a canonical background: $1\ was = 60\ šā· = 240\ mu = \text{ca. } 252\ \text{L}$. Far bigger than this *mudd* (ca. 1.05 L) of Medina were the *mudd* of Egypt and Iraq (2.5 L), of Syria (3.67 L), of the Maghreb (4.32 L), and that of Jerusalem (100 L). The prophetic *šā·* was exactly 4.2125 L. Being the quantitative lower limit (*nišāb*) for the liability for the *zakāt* (alms) taxes, the measure of five *wasḳ* of dates, for example, was equated in value with five *ūḳīya* (= 200 *dir* = 529.9 g), 20 *dī* (or *mithḳāl*, = 84.7 g, see later), five *dhawd* (camels), the *nišāb* of cotton (5 *was* = 1, 600 *dir* · *irāḳī* à 130 g), or 50 *kay*. Therefore, the values given for one *wasḳ* greatly differ. In the time of Hārūn al-Rashīd (around 800), a short-lived *wasḳ* (1 *was* = 2 1/2 prophetic *was*) was introduced.

Towards the end of the seventh century, the *ḳaf īz* (usually corresponding to $1/10\ dj = 1/60\ kurr$) was used instead of this prophetic *šā·* in Iraq. Another specific *ḳaf īz* of capacity is recorded from Iraq around 990: $1\ ḳa = 1\ ḳaffa$ (basket) = $1/2\ zabīl$ (basket made of palm leaves).

In Egypt grain, but in particular wheat, was measured by *irdabb*: $1\ ir = 6\ wa = 24\ ru = 48\ ḳad = 90\ ma = 96\ ḳad$ (small) = ca. 90 L. Different values extant for the *irdabb* (between

72.3 kg, modern 182 L) may be explained also by the difference of volume between, for example, wheat, barley and lentils (100:80:104).

Egyptian flour was measured in *tillīs*: $1\ ti = 3/2\ wa = 3\ ba = 15\ ma = 24\ ḳad = 22.5\ \text{L}$. There, the *waiba* of rice (1 *wa* = 8 *ḳad* = 24 *r kabīr*), as observed around 1665, contained only 12.5 l. Three centuries before in Tunis, it was equal to 12 prophetic *mudd* (ca. 12.6 l).

In Medina and Iraq, honey but also wheat was measured in *farḳ*: $1\ fa = 3\ ša = 36\ r\ bagdādī = 19\ \text{L}$. In Egypt and Syria, the *mudy* – not to be confused with the *mudd* – replaced the *ḳisṭ* when not oil but food was measured. It is sometimes called 'the Syrian *djarīb*', sometimes equated with the *ḳaf īz*. The practice in Syria, however: $1\ ḳa = 8\ mak = 12\ ša$, the indication: $1\ mud = 15\ mak = 22\ 1/2\ ša$ does not confirm this. In Palestine, a square *mudy* was known ($1\ mud^2 = 1\ ḥab \cdot 1\ ḥab$).

Olive oil was merchandised in *maṭar* (1 *maṭ* = 2 *ḳu* = ca. 17 kg) in the Maghreb, in *ḳulla* (1 *ḳu* = 12 *th* = 27 *r* = 13.6 kg) in Andalusia. In Egypt, the *thumn* corresponded to $1/8\ ḳad$ (today 0.29 L), in Qayrawān to 6 prophetic *mu* = 6.32 L. Oil and other liquids were also measured in *ḳisṭ*: In Iraq, the 'small' *ḳisṭ* (1 *ḳi* = 3 *r* = 1.22 L) was half of the 'great' *ḳisṭ*, in Egypt it was half of a *šā·*: 211 L; elsewhere the *ḳisṭ* is given as: $1\ maṭ = 4\ ḳi = 21\ 1/3\ r\ djarwī$ (see below) = 192 *ūḳ* (capacity) = 256 *ūḳ* (weight). In Andalusia, wine and vinegar were sold in *rub·* (1 *ru* = $1/4\ ḳad = 18\ r = 216\ ūḳ = 1,728\ mi = 8.16\ \text{L}$, in Persia the *peymāne* (bowl, 8.3 L) was in use for this purpose. In Iraq, wine, but also oil and honey, were measured by *makkūk* or *mishḳā·* (drinking-vessel): $1\ mak = 48\ th \text{ à } 50\ dir = 64\ mish \text{ à } 37\ 1/2\ dir = 7.5\ \text{L}$.

Another widespread unit of capacity was the *ghirāra*, mainly used for grain: $1\ ghi = 3\ ir\ miṣrī = 12\ kay = 14\ mak = 72\ mu\ dimashḳī = 73\ 1/2\ mu\ miṣrī = 265\ \text{L}$. In Egypt, the *kayla* = 8 *ḳad* was 7.5 L (modern 16.5 L).

This *kayla* is not identical with the *kayladja*, presumably an originally Persian unit of capacity measure: $1\ kayl = 1/2\ ša = 1/3\ mak = 3/14$

$ghi = 1/6 \text{ } \bar{ka}$ wheat = $1/5 \text{ } \bar{ka}$ barley = ca. $1 \text{ } 7/8 \text{ } ma = 2.5 \text{ L}$ (or 2 L in East Iran).

The most basic of all grain measures, especially in the Islamic East, was the old Babylonian *kurr*.

$1 \text{ } ku = 30 \text{ } \bar{ka} = 60 \text{ } \bar{ka} = 480 \text{ } mak = 600$
 $'ushr'as = 1,440 \text{ } kayl = 5,769 \text{ } ru = 7,200$
 $r = 11,520 \text{ } th = 2,925 \text{ kg}$ (wheat).

Smaller than this 'big' *kurr* of Baghdad was the *kurr* of Wāsiṭ and Baṣra ($1 \text{ } ku = 60 \text{ } \bar{ka} = 480 \text{ } mak = 1,440 \text{ } kayl \text{ } \bar{a} \text{ } 600 \text{ } dir$ of wheat = $2,700 \text{ kg}$); a 'reformed' *kurr* even amounted only to: $1 \text{ } ku = 60 \text{ } \bar{ka} \text{ } \bar{a} \text{ } 25 \text{ } r \text{ } baghdādī = 609.375 \text{ kg}$ (wheat). Moreover, depending on the kind of grain measured, different *akrār* were used: In fourteenth century Baghdad, the *kurr* of wheat weighed $2,925 \text{ kg}$, that of barley $2,437.5 \text{ kg}$, and that of rice $3.656,25 \text{ kg}$. The common sub-units of the *kurr*, the *ḳaf īz*, *makkūk*, *kayladja*, and *thumn* differed respectively, sometimes not only proportionally. Thus, in twelfth century Aleppo, a quite different *makkūk* existed: $1 \text{ } mak = 19 \text{ } sun = 28.5 \text{ } r \text{ } \bar{a} \text{ } 684 \text{ } dir \text{ } \bar{a} \text{ } 3.125 \text{ g} = 60.92 \text{ kg}$. About the same time, the *ḳaf īz* of ḥamāh was $7/8 \text{ } \bar{ka}$ of that of Shayzar. In Aleppo, $4 \text{ } mak$ made one *marzbān* ($1 \text{ } mar = 1/4 \text{ } mak = 19/4 \text{ } sun = 57/8 \text{ } r = 4,873 \text{ } 1/2 \text{ } dir = 15.23 \text{ kg}$).

Towards the end of the tenth century, the mathematician al-Būzjdjānī compared the new 'reformed' (Arabic *mu·addal*) *djarīb* – this *djarīb* was not measured with 10 but with $2 \text{ } 1/2 \text{ } \bar{ka}$ only – which was introduced after 978 by his Lord, the Būyid ‘Aḏud al-Dawla, with four different common types of the *kurr*. His systematic treatment of the issue will throw some light on the complex variety of the units used and their specific relation when being transformed from one into another (see matrix below).

Besides *simsim* (sesame), *ḥinṭa* (wheat), *djahkandam* (mixture of $1/2 \text{ } ḥinṭa + 1/2 \text{ } sha·īr$), and *sha·īr* (barley), a fifth category is formed to include all kinds of grain and dry goods that do not belong to one of the aforementioned categories: nuts, like almonds, pistachios and hazelnuts,

dried pears, plums etc. From the matrixes 1–4, exactly 280 possible combinations result by which the transfer of one given quantity (and value) of one commodity into another can be calculated.

Example

If 24 *ku* of oats (*ḥurṭumān* = category of *shaṭīr*) should be transferred into *kurr sulaymānī* of pepper grass (*ḥabb al-rishād* = category of *ḥinṭa*), then the rule of seven is required, in short:

$$24 \text{ ku } kāmīl \text{ shaṭīr} - 1/6 \cdot 24 = 22 \\ \text{ku } sulaymānī \text{ ḥinṭa} + 30 \text{ ḳa}.$$

Measures of Weight

The entire Islamic system of weights is based on the *dirham* and the *raṭl*. The *raṭl* is the most common smallest unit, or reference, of weight. The weight of the *dirham* is used for two different purposes. The two values differ correspondingly:

Dirham al-fiḍḍa (Silver Dirham)

Calibration of the silver (*dirham*) and gold (*dīnār*) coins was done with the help of glass weights. The earliest preserved exemplars date back to the second half of the eighth century. The *dirham* weight defined the weight of the *dirham* coin, the *mithkāl* weight the weight of the *dīnār*. The most precise glass weights of the *mithkāl* have an average weight of 4.233 g (max. tolerance 1/3 mg). Archaeological finds affirm both the weight of the *dirham* in accordance to the canonical ratio of *dirham*: *mithkāl* (= 10:7): 2.97 g, as to the 'rounded' ratio (= 3:2): 2.82 g. An exceptional *mithkāl* weight was in use in Egypt under the Ayyubid dynasty and in the Maghreb under the Almohad dynasty (4.722 g).

The *mithkāl* gold and the *dirham* silver were divided into *ķīrāṭ* and *ḥabba*.

$$1 \text{ mi gold} = 20 \text{ ķī} = 60 \text{ ḥa}; \\ 1 \text{ dir silver} = 12 \text{ ķī} = 48 \text{ ḥa (Iraq)}$$

$$1 \text{ mi gold} = 24 \text{ ķī} = 60 \text{ ḥa};$$

$$1 \text{ dir silver} = 16 \text{ ķī} = 60 \text{ ḥ (Arabia, Egypt, Syria)}$$

Hence, the values (see matrix below).

In addition to these general systematic differences a variety of deviating systems from different regions, authors and periods are recorded (tenth to thirteenth century; indicated as I–V), that integrate sub-units like the *dāniḳ*, *ṭassūdj*, *ashīr*, *fals*, and *aruzza* (which elsewhere corresponds to 25 *ḥa ḥardal*, grains of mustard, i.e. ca. 0.0186 g); one author defines the *ḥa ḥardal* as 1/70 of a *ḥabba* (which is sometimes replaced by '*ḳamḥa*', grain of wheat), 60 of which make one silver *dirham*, i.e. 1 *ḥa ḥardal* = 0.0007 g. From the vague comments of sources, it must be assumed that most of these different systems were in use as weight measures too (see matrix below).

According to the actual ratio of value between gold and silver currency, the moneychangers had to take several factors into consideration when transferring amounts of money from one currency into the other. This could result in thirteenth century Egypt, for example, when 16 4/5 *dir* were equivalent to 1 *dī*, in the following calculations:

$$1 \text{ dī} = 1,440 \text{ ḥa fiḍḍa} [10 \cdot 60/7 \cdot 16 \text{ 4/5} = 1,440]; \\ \text{and} \\ 1 \text{ ḥa gold} = 1/5 + 2/25 \text{ ķī} = 16 \text{ 4/5 ḥa silver}; \text{ or} \\ 1 \text{ fa} = 2 \text{ 2/5 ḥa silver} = 1/7 \text{ ḥa gold} [2 \text{ 2/5} : \\ 1/7 = 16 \text{ 4/5}].$$

Dirham al-kayl (Weight Dirham)

In contrast to the homogeneous evidence of the weight of the 'silver *dirham*' the extant values of the weight of the 'weight *dirham*' deviate considerably from one another. They range from 3.086 to 3.148 g. When not indicated otherwise, the following comments will be based on the established average standard value of 1 *dir* = 3,125 g with which the 'canonical' (ratio 10: 7) *mithkāl* of 4.464 g is corresponding. From textual evidence some of which are included in the matrix above, different regional values of the *dirham*/*mithkāl* weight can be deduced:

Egypt 3.125/4.68 g; Syria (Aleppo twelfth century) 3.14/4.427 g, (Aleppo nineteenth century) 1 *dir* = 3.167 g, Damascus 3.086/4.62 g; Anatolia (Ottoman period) 3.086/4.81 g; Iraq 3.125/4.46 g; Iran (fourteenth century) 1 *mī* = 4.3 g, (sixteenth century) [3.26]/4.639 g; Maghreb 3.3/4.722 g; East Africa (sixteenth century) 1 *mī* = 4.41 g.

With the exception of Persia, where the *mann* dominated the system of weight measures, the *raṭl* became the most common and widespread unit of weight measure in the Islamic world, comparable in size and function to the European ‘pound’ (Pfund, livre, libra, Italian loan word ‘rotolo’). The *raṭl* was measured in *dirham*. Depending on what was measured, and where and when, the *raṭl* could take different numbers of *dirham* (values between 96 and 1.040 are recorded) of different *dirham* weights (standard value: 1 *dir* = 3.125 g).

If integrated into the early Meccan system:

1 *r* = 2 *ma* [à 130 *dir*] = 12 *ūḳ* = 480 *dir* = 1/100 *ḳin*,

the *mithḳāl* weights produce the following (fictitious) relation:

1 *mi* = 20 *ḳī* = 60 [or 100] *ḥa* = 10/7 *dir* = 1/336 *r* (for Iraq; 1 *ḳī* = 0.223 g)
 1 *mi* = 24 *ḳī* = 96 *ḥa* = 3/2 *dir* = 1/320 *r* (for Mecca, Egypt etc.; 1 *ḳī* = 0.195 g).

From archaeological (glass weights) and textual evidence, several hundred *raṭl* weights are known. The following list enumerates (in order of size, with ‘[...]’ values developed) some of the standard *raṭl* weights repeatedly recorded (see matrix below).

Besides the *raṭl*, the *mann* was an important unit of weight everywhere in the Islamic world, in particular in the Persian East, where it weighed between 260 *dir* (= 816.5 g) and 2,080 *dir* (= 6,656 g). A similar variety of *mann* weights was used in Asia Minor (twelfth century onwards). Until the fifteenth century it was used instead of one half of a *raṭl* à 130 *dirham*. Then a ‘big’ *mann* (ca. 3–3.25 kg), and a ‘middle’ *mann* of 1.920 g

came into use. During the Safawid period (sixteenth century), a ‘super’ *mann*, later called the ‘royal’ *mann* (between 5.7 and 6 kg), was introduced. The Ottomans used the *okḳa* (1 *ok* = 2 *nu* = 400 *dir* à 3.207 g = 1.2828 kg) instead of the *raṭl*. Its stability was proverbial: *Okka her yerde dört yüz dirhem gelir* (... to be no different from anybody else).

The biggest unit – besides the rather colloquial *ḥiml*, camel-load (1 *ḥi* = ca. 250 kg) – was the *ḳinṭār*, the hundredweight (= 100 *r*). Depending on the type of *raṭl* it was based on, the *ḳinṭār* weights differed. In medieval Egypt, different *ḳinṭār* weights were common: *fulfulī* (pepper) = 100 *r* à 144 *dir* = 45 kg; *laithī* = 100 *r* à 200 *dir* = 62 kg; *djarwī* = 100 *r* à 312 *dir* = 96.7 kg; *mannī* = 100 *r* à 260 *dir* = 81.25 kg; ‘big’ = 24 *ru* = 240 *r* à 160 *dir* = 38,600 *dir* = 120 kg. In a treatise composed by a customs officer in the thirteenth century, additional *ḳinṭār* names, but no values, for specific goods are mentioned. While the *ḳinṭār* of Syria (Aleppo, ḥimṣ, ḥamāh) was always equivalent to 100 local *raṭl*, it was taken for 100 *mann* in late medieval Iraq. In Iran (fifteenth century) and Asia Minor (Ottoman period) 1 *ḳinṭār* weighed ca. 57 kg.

The smaller weight unit of *istār* (1 *is* = 4 1/2 *mi* = 6 3/7 *dir* = 20.07 g), only known from Egypt, was used there to weigh silk: 1 *s-ḳ-ṭ* [?] = 3 *ru* = 90 *man* = 180 *is*.

The Quranic ‘*ḥabba min ḥardal*’ (the ‘grain of mustard’, see above), being 1/70 *ḥa* of 1/60 *dir* each (= ca. 0.0007 g), seems to have remained the smallest unit of weight in use in the Islamic world. If calculated properly, the fictitious *naḳīr* (1 *djo* = 6 [ḥa] *ḥardal* = 72 *fa* = 432 *fāl* = 2,592 *na* = 1/96 *mi* = 0.045 g) would correspond to ca. 5 ng.

al-Ḳurashī

The research of the history of weights and measures and their use in the Islamic world is based on a variety of sources. Unfortunately, no particular literary type of text developed that could

claim to be called ‘professional’. The information available is scattered over texts on law, social and economic history, administration and geography. They generally lack a systematic character, i.e. ignore comparative and proportionate references. The most recent endeavor to collect all information available in the historical sources was undertaken by Maḥmūd Fākhūrī and ṣalāḥ al-Dīn knawwām in: *Madjmūʿ at waḥdāt al-qiyās al-ʿarabīya al-islāmīya*, Beirut: Maktabat Lubnān Nāshirūn, 2002. Only occasionally, external sources, records of both European and Oriental travellers, allow the fixation of absolute values. With regard to their geographical and chronological diversity, the reconstruction of entire systems of measurement and of their relation to each other has just begun.

Aleppo: weights

During the tenth century, mathematicians became aware of the complexity of the metric systems in use. Their particular perspective on the issue differed from what their legal and other colleagues had been noting down hitherto. They not only tried to present a systemized enumeration of all units related, but also endeavoured, for pedagogical reasons, to systematize the usage of measuring units in popular treatises. They sometimes even expressed efforts to standardise and facilitate the conversions customs, market and tax officers had to enact. Thus, stimulated by theoretical manuals, mathematically standardised methods of measuring and of converting quantities from one system into another became popularised. To some extent, these devices even had retroactive effects on the practice of Islamic laws.

Among these manuals, the “Book on the Basis of Arithmetic and the Division of Inheritances” (*Kitāb al-Tadhkira bi-uṣūl al-ḥisab wa l-farāʿid*), written by the Damascene mathematician ‘Alī

b. al-Khiḍr al-ʿUthmānī al-ḡurashī (1030–1067 AD) contains the most coherent information on the metric systems that were in use in the Islamic Middle East up to the lifetime of the author. The following list of units of weight, currency, capacity and length, together with the localities they refer to arranged in alphabetical order, is extracted and, if indicated by ‘[...]’, concluded from different chapters of this *Kitāb al-Tadhkira*.

Egypt (Abbasid period)	96 dir	300 g
Rūmī (Asia Minor) I	102 6/7 dir	321.43 g
Umayyad period	[110 dir]	340 g
Rūmī (Asia Minor) II	120 dir	375 g
Iraq (medieval)	128 4/7 dir	401.79 g
Abbasid period (Egypt, Baghdad)	130 dir	406.25 g
Maghreb	130 dir	406.25 g
Maghreb	137 1/7 dir	428.57 g
Umayyad period (Egypt)	[140 dir]	437.5 g
Maghreb (Fāṭimid period)	140 dir	437.5 g
Egypt (later Abbasid period)	144 dir	450 g
Fulfulī	150 dir	468.75 g
Maghreb (Ibn Baṭṭūṭa)	150 dir	468.75 g
‘big’ Egypt (Abbasid period)	160 dir	500 g
Maghreb (Ibn Baṭṭūṭa)	180 dir	562.5 g
Laithī	200 dir	625 g
Djarwī	312 dir	975 g
Turkestan (fourteenth century)	330 dir	1,031.25 g
Fes/Marrakesh (fourteenth century; = 16 ūḡ)	336 dir	1,050 g

(continued)

Aleppo (twelfth and thirteenth century)	480 <i>dir</i>	1,500 g
Syria/Palestine (fourteenth century)	592 1/2 <i>dir</i>	1,851.56 g
ḥimṣ (twelfth century)	684 <i>dir</i> [sic]	2,137.5 g
Aleppo (after thirteenth century)	[724 <i>dir</i>]	2,273 g
Jerusalem (medieval)	800 <i>dir</i>	2,500 g
ḥimṣ (Syria, medieval)	864 <i>dir</i>	2,700 g
Constantinople (eighteenth century)	876 <i>dir</i>	2,800 kg
Jerusalem (nineteenth century)	900 <i>dir</i>	2,812.5 g
Iran (Shīrāz, Fārs; in <i>mann</i>)	1,040 <i>dir</i>	3,250 g
Sivas	1,440 <i>dir</i>	4,618 g

Weights and Measures in Japan

Shigeo Iwata

Japan used the 17.3 cm-long linear measure unit that was common to all the regions in East Asia for a period of 25,000 years. Under the influence of China, the Japanese measuring unit gradually lengthened during the period from the end of the eleventh century BCE to the middle of the third century BCE. Then, the length of the Japanese measure *shaku* was stabilized at 23 cm and remained unchanged until the end of the second century AD. Various civil disturbances in China had the effect of lengthening the linear measure substantially to 29 cm until the middle of the seventh century, and no more significant variation has since been observed (Fig. 1).

Length

Under the Chinese Tang dynasty, a law was enacted mandating the use of two methods based on large and small linear measures. The large scale was 1.2 times as long as the small scale, which we refer to as the ancient linear measure. The small scale was used for music, astronomy, and ceremonial items.

Japan introduced this Chinese measuring system in 701. The large scale later became known as *kanejaku*, which refers to an L-shaped ruler used by architects. The small scale gradually dropped out of use. Linear measurement tools were mainly made of wood, though ivory was also used in ancient times. The largest unit of length in ancient times was the *ri*, which was 5–70 *cho* (a *cho* was 109.1 m). The *ri* was set to

Weights and Measures in Japan, Fig. 1 Linear measure (Drawing by The Ministry of Finance. *Doryoko Shurui Hyo* (The Classification Table of Weights and Measures) Genbei Kinokuniya, 1875. Chos 1, 4–6, 9–11)

36 *cho* in the seventeenth century. One *shaku* was one-tenth of a *jo*. Metal linear measurement tools began appearing in the medieval era.

The average value of one *shaku* was 29.6 cm in the seventh century, 29.7 cm in the eighth century, 29.8 cm in the ninth century, 29.9 cm in the tenth century, 30.1 cm in the twelfth century, 30.2 cm in the fourteenth century, and 30.3 cm in the eighteenth century. The rate of elongation was slower than in China.

Several linear measures for sewing appeared in the medieval era. The length of one *shaku* ranged from 1.15 to 1.27 times that of a *kanejaku*. These linear measures for sewing were neatly arranged into two kinds of scales. One scale,

1.20 times as long as a *kanejaku*, was called *gofukujaku*, while the other was 1.25 times as long as the *kanejaku* and called a *kujirajaku*. The *gofukujaku* gradually dropped out of use in the first half of the eighteenth century and was finally abolished in 1875.

Area

The earliest area unit we know of was the *shiro*, which was in use before the sixth century. One *shiro* was 30 *shaku* square. In 646, new units were defined: the *bu*, which was six *shaku* square; the *tan*, equal to 360 *bu*; and the *cho*, equal to ten *tan*. One *tan* has been equal to 300 *bu* since the end of the sixteenth century. For land surveying purposes, one *bu* was defined as six *shaku* five *sun* square, rather than six *shaku* square. At the end of the sixteenth century, a *bu* was defined as six *shaku* three *sun* square. Despite this, the *bu* was commonly considered to be six *shaku* square, and was finally defined as such in 1891. A *se* was ten times as large as a *bu*, which was also referred to as a *tsubo*. These names appeared in the medieval era. Land surveyors made their measurements using flax string measures and wood measuring poles (Figs. 2 and 3).

Volume

The names for most units of volume also came from China. The basic unit was the *sho*. One *sho* averaged 750 cm³ in the eighth century, 800 cm³ in the ninth century, 970 cm³ in the eleventh century, 1,400 cm³ in the fifteenth century, and 1,650 cm³ in the sixteenth century. Since the seventeenth century, the average value has remained constant at 1,804 cm³. During the medieval era, different measures of volume were used for goods, taxes, and financial transactions (Fig. 4).

The Tokugawa-Shogunate (1603–1867) established the ► [East and West Measure Guilds](#) in 1655, and exerted strong control over the new standard. Use of *sho* continued until 1958, when the *shaku-kan* system was abolished.

Weights and Measures in Japan, Fig. 2 Land surveying (From *Tokugawa Bakufu Kenchi Yoryaku* (Essential summary of the Government of prefectures, Tokugawa Shogunate). Tokyo: Kashiwa Shobo, 1915)

Rectangular measures were made of wood. The brims of many dry measures were protected by ► [bamboo](#) or iron laminae. Most of the large dry measures also featured a narrow iron bar positioned diagonally across the top. Round wooden sticks were used to level off the tops of measures. Liquid measures had lacquered surfaces to prevent the contents from leaking.

Standard sizes for measures have been one *to*, seven *sho*, five *sho*, one *sho*, five *go*, two *go* five *shaku*, and one *go* since 1655, and one *to*, five *sho*, one *sho*, five *go*, two *go* five *shaku*, one *go*, and five *shaku* since 1875.

Mass

Between the eighth century BCE and the fifth century AD, the Chinese expressed mass in terms of the *liang*, which was equal to 14 g. In this measuring system, one *jin* was equal to

16 *liang*, and one *liang* to 24 *zhu*. The civil disturbances of the third and seventh centuries also had their effect on the *liang*, which tripled in mass. Under the Chinese Tang dynasty, a law stipulating two measuring scales was enacted, which fixed the mass of the new large *liang* at three times that of the mass of the older *liang*, which became used only for medicine.

Japan adopted this Chinese measuring system as well, changing the names of *jin*, *liang*, and *zhu* to the *kin*, *ryo*, and *shu*, but retaining the same characters. The absolute mass of the *ryo* in the large scale decreased year by year, while that in the small scale became rather unclear. The average mass of one *ryo* was 42 g in the eighth century, 40 g in the tenth century, 39 g in the twelfth century, and 37.47 g at the end of the sixteenth century. Under the strong control of the Tokugawa-Shogunate, the average mass of the *ryo* remained almost unchanged until the end of the nineteenth century. The *kan* and

Liquid measure

Dry measure

Weights and Measures in Japan, Fig. 3 Measures (Drawing by The Ministry of Finance. *Doryoko Shurui Hyo* (The Classification Table of Weights and Measures) Genbei Kinokuniya, 1875. Chos 1, 4–6, 9–11)

monme appeared in the medieval era. One *kan* was equal to 100 *ryo*, and one *monme* equal to one-tenth of a *ryo*. These units gradually became standard.

Chinese use of the steelyard dates back to at least several centuries BCE. The steelyard was also used in Japan, where the Tokugawa-Shogunate established the East and West Steelyard Guilds in 1653. Steelyard beams were made of white oak, persimmon wood, ivory, horn, and bone. The beam had from one fulcrum to eight fulcra, which were made using string, cord, or rope. A copper pan or bronze hook was installed on the end of the beam, and the bob-weight was made of bronze or iron. Steelyards were used for most commercial transactions (Fig. 5).

Balance makers did not belong to a guild, so standards for making balances were never formulated. The most famous balance makers were

members of the Nakabori family, who lived mainly in the western counties of Japan. The balance beam was suspended by its pointer from the center of a box-mounted rectangular wooden stand. A central pin was used for the main fulcrum, and during the final stages of weighing, bearing friction was overcome by tapping on the pin with a small wooden hammer. Balances were mainly used in the manufacture of gold, silver, and copper coins, and in money-changing transactions.

Beginning in the seventeenth century, users of the balance had to be supplied with weights made by the Goto family. Two sets of weights were available: one consisted of weights of 20, 10, 5, 4, 3, 2, 1 *ryo*, 5, 4, 3, 2, 1 *monme*, and 5, 4, 3, 2, 1 *fun*, and the other was identical to the first but for the addition of 50 and 30 *ryo* weights. Weights were made of bronze, and engraved on the surface with the inspector's mark and maker's crest, leaves

Weights and Measures in Japan, Fig. 4 Steelyard (Drawing by The Ministry of Finance. *Doryoko Shurui Hyo* (The classification table of weights and measures) Genbei Kinokuniya, 1875. Chos 1, 4–6, 9–11)

and flowers of the Japanese paulownia. The Goto family belonged to the Guild of Goldsmiths, and were inspectors authorized by the feudal government. They examined user's weights periodically by comparing them with standard weights.

Transition to the Metric System

In 1886, Japan signed the Treaty of the Meter, and promulgated the Law of Weights and Measures. As a result, the *shaku-kan* system and metric system began to be used jointly in 1891. The conversion coefficients between these two measuring systems were also fixed at the same time (Table 1). The law went into formal effect in 1893. In 1903, the Central Inspection Institute of Weights and Measures was established in Tokyo. Japan also adopted the units of the foot-pound system as legal in 1909.

					1		10	0.0375 g
							1	0.00375 g

A Measurement Law was passed by the Diet in 1951, and went into effect on March 1, 1952. It mandated that measuring units be based on the metric system. The *shaku-kan* system and foot-pound system were abolished in 1958.

A new Measurement Law was promulgated on May 20, 1993, and went into effect on November 1, 1993. The law made a sweeping revision of the regulations by adopting the *Système Internationale d'Unités*. The units of the other measuring systems on commercial transactions and certifications were abolished by the end of the twentieth century.

Weights and Measures in Mesoamerica

Jean-Claude Hocquet
Centre National de la Recherche Scientifique,
University of Lille, Lille, France

Indian Measures

In Latin America, the Indian populations measured and counted the goods, lands, merchandise, and the days and months according to scientist systems that historiography began to decrypt. After the Spanish conquest, the conquerors imported the weights and measures of their country, the Castille, which, itself, had borrowed a good part from the Arab-Berber occupants (Villena). In Mesoamerica, in Mexico in particular, the result was a new syncretism which merged the different systems. The Indians adopted the measures of the conquerors who did not hesitate to attribute Indian names to the new measures.

“Los aztecas tenían una fuerte tendencia a medir y contar” [The Aztecs had a strong tendency to measure and count] (Harvey and Williams). The arithmetic system was based on three major numbers: 20, 400, and 8,000. The number 20 is called “a count” (*cempoalli* in Náhuatl language), $20^2 = 400$ or “a head of hair” (*centzontli*), and $20^3 = 8,000$ “a bag” (*cen-xiquipilli*). The system was vigesimal. The pictograms representing these three numbers used the glyphs “banner” (*pantli*, 20), pen or stylized “hair” (*tzontli* 400), and “bag of copal or incense” (*xiquipilli* 8 000). For quantities of less than

20, the populations of the highlands used a small white circle for the number 1, and five of these circles united by a lower stroke for the number 5. The integers between these positions (20, 400, 8,000) were of the quantities which could be added or multiplied. Thus, 49 is represented as “2 count and 9” and 500 as “a head of hair and 5 counts.” (Royas Rabiela). The numbering system was “from a position of line and point and employed only four symbols: the vertical line, five circles linked by a line, the point, and the glyph of maize, with position indicative of the value of the symbol to represent the function of zero.” The Mayas and the Zapotecs employed the point for 1, one bar for 5, and four bars for 20, and they created a sign for zero. With these three signs they represented any quantity.

The calendars were a measure of the time and recorded the days, weeks, months, years, and centuries (in fact the generations) from the astronomical observation of solar, lunar, and Venusian phenomena. The higher cycle (century) or Venus cycle lasted 52 years and combined two calendars, one of 260 days and one of 365 days. The first was the ritual calendar of 13 periods of 20 days each; the other was a solar calendar of 18 periods of 20 days, more than a short period of 5 days. The period of 20 days was a month. The combination of the two calendars was allowed to repeat the same date to 52 years or a “century.” This Maya system recorded the time with great accuracy.

The measures of length were modeled on the human body, the more common unit of length was the “fathom” or “toise” (*cenmaitl*, literally a “hand”), the distance between the fingers of two arms apart in the horizontal position. It was used to measure fields, houses, streets, and canals and on maps drawn up for economic or tax purposes. The other measures were submultiples. There also existed a vertical “toise,” measured from the foot to the high arm vertically and a cubit which meant the distance between the elbow and the fingers outstretched to the other arm. The fields were also measured “on the rope,” and the measurement of standard area was a *mecatl* of 400 (20×20) mecate squared (Matías Alonso).

Weights and Measures in Mesoamerica, Fig. 1 Workers prepare the land (perhaps a swamp to dry up) and level it; the surveyors measure with the rope, and the king handles the distribution of the fields (Source: Teresa Rojas Rabiela, p. 43, after the Códice Durán,

Historia de las Indias de Nueva España e Islas de Tierra Firme written in the second half of the sixteenth century by the Dominican Diego Durán and conserved in the Biblioteca Nacional de España)

The various peoples of Mesoamerica did not seem to weigh the goods (products) and did not have scales, and Hernán Cortés, the conquistador, had the opportunity in 1529 to see the market of Tlatelolco, and the transactions which went on there. He wrote, “everything is sold by count and measure, and up till now I haven’t seen anything sold by weight.” Yet the concept of “load” (*tameme*) was in common usage; it meant the mass a porter (*tlamamalli*) could carry in a day. It therefore combines a time measurement and a unit of mass evaluated by the carriers who raised it and an empirical adjustment, by taking into account the distance to browse. In sum the load was a measure adapted to the labor force of the bearer.

For volume, each product had its specific measure. Maize or beans were measured in “loft (granary),” honey in *cantars* of 100 lb (from Latin *centenarium*), cotton in bales, cocoa in loads, and salt in “bread.” So the level of development attained by the Mesoamerican people before the Conquest makes it very likely that they had an ensemble of measures and standards

used in the apportionment of land, commercial transactions, levying of taxes, construction, pharmacy, etc., and that these measures constituted unified and coherent systems.

Teresa Rojas Rabiela, from whom we borrow this information, states that she has only attempted an outline on a field still overlooked. The modesty of her judgment must not hide the fact that the measures of surface and capacity (volume) remained in wide use and the majority of the Indian population has remained faithful to the measures and ancestral practices (Fig. 1).

Weights and Measures of New Spain

In the sources of the eighteenth century, the range of different names involved – *carga*, *fanega*, and *arroba* or *brazas*, *codos*, and *varas* – hides the numerical relations which link multiples and sub-multiples. The *carga* is made up of two *fanegas*, composed in turn of six to eight *arrobas* (García Acosta, Hocquet). In general, the

historian goes from the largest to the smallest, whereas in practice, the peasant, the muleteer, or the trader proceeds in the reverse order. In the same way that the metric *quintal* is made up of grams and kilograms between which the factor ten governs all relations, in the eighteenth century, two and six (equals two multiplied by three) governed the relations of the *carga* with its sub-multiples. The decimal metric system is a scientific system, mathematic in character, invariant, exterior to humans (Hocquet 1995). In contrast, previous systems were based on people or on observations concerning them or on their work and capacity to complete certain tasks with the aid of animals. That is, if a mule must climb steep paths with its load, the muleteer compensates for this by lowering the weight of the load by one or two *arrobas*. At times, the sources mention *cargas pequeñas* in contrast to *cargas regulares de mula*. "As long as freighting relied chiefly on pack trains and carts, the weight of the loads was determined by distances to the customer, the availability of pasture *en route*, as well as by the nature of roads and tracks. In the case of steep mountain paths, broken country or long distances, the *carga*, the traditional load of a mule, could be lowered in weight. So a mule load could comprise one and a half or two *fanegas*. In 1832 the Governor of Oaxaca stated that because of the poor roads the *carga* could never consist of more than eight *arrobas*" (Ewald). Generally the custom of mentioning the number of *arrobas* making up a *fanega* or a *carga* does not eliminate the uncertainties which surround all quantitative data. In 1751, the *carga* of salt in Tehuantepec consisted of 14 *arrobas*. Another eighteenth-century source stated that moist Tehuantepec salt was 16 *arrobas*, while drier salt was computed at 12–14 *arrobas*. The dampness or dryness of goods being transported markedly affects their weight. The presence of water increases the weight of light goods such as grains, but it lessens the weight of heavier ones, in particular salt. In Tehuantepec, the variation in weight often reached a quarter.

But there is another trap: Ralph Roys, for example, noted that a *fanega* "is variously

defined as 1.6 bushels, and a load of 100 lb of grain," which is an example of recent efforts to align traditional measurements with those of the national market governed by the decimal metric system, while at the same time conserving the ancient names. But this statement has led a number of scholars to assume that a *fanega* weighs 100 lb, which is seldom the case. The *fanega*, like the bushel, is a measure of capacity, not weight. It is important not to confuse measures of capacity, which are volumes, and units of weight which measure mass: weighing the contents of a volumetric measure can only lead to considerable distortions, since each body (or matter) has a specific weight by which it distinguishes itself from all others. The foreigners who traveled or worked in nineteenth-century Mexico reported that a *fanega* of salt weighed approximately 70 kg and a *carga* 140 kg. The nineteenth-century sources gave 300 lb as the equivalent of a *carga*. The historian will recognize the mule load of 300 lb and the 16-ounce pound, such familiar territory that he would think he was in Castile in the time of the Catholic Kings (Gual Camarena).

A New Synthesis

The Spanish imposed Andalusian and Castilian measures that the Indians adopted easily, because, like their own, they were anthropometric. The result of this adoption was that Mesoamerican symbols of measure were transcribed in European terms on the pictograms of indigenous manuscripts written in the Náhuatl language (Alonso, Castillo Ferreras). Bars represented digits, little black circles were for 20s, and other signs represented hands or feet. Thus, to go back to the example of the "*carga*" already cited, the Indians gave the name *tlamamalli* to the load (*carga*) that a *tameme* (porter) could carry on his shoulders during a day's work. In the *novohispano* system, this load had the name *tameme*, by a simple movement of language and meaning. It was equivalent to a Spanish *half-fanega* or to two *arrobas*.

This indigenous load varied in weight, in the function of the weighed merchandise, and with the strength of the carrier: for cocoa it was equivalent to three *xiquipilli* of 8,000 grains each, and it is clear that there is a mixture between Indian and Hispanic measures.

Among the measures of capacity, of great diversity, the smallest were the *centlachipiniltontli* (*una gotilla de algo*) and, its multiple, the *centlachipinilli*, which literally means “a small something” (*una gota de algo*). There were also small measures used in pharmacy, such as spoonfuls (*cemixcolli*, *cenxumatli*, etc.). *Testal* designated the quantity of cornmeal necessary to make a tortilla for one person. The concept of mass had more to do with daily people’s usages than with practical knowledge of balance and weights.

To measure dry materials, in particular for grains, they were often able to use measures equivalent to those imported from Spain: the *acalli*, for example, of which we do not know the weight, was part of an arithmetic system with the *cencaauhacalli* equal to a *half-fanega* and with the *cuauhacaltontili* equal to a *celemin*. Such equivalent approaches make it possible to conclude that the conquerors tried to impose their own system while at the same time adopted the native terms.

Measures of length were used for the fabrication of clothing, especially for ponchos, made of bands of different widths. Most measures of length were based on proportions of the human body: *cemiztehtl*, *cemmapilli*, and *cemmatl*, literally a finger, a palm, and a span. This “span” designated the height of a man, from foot to raised hand, but it also measured the diagonal, from the left foot to the raised right hand, and it stood for three Spanish *varas* (yards or cubits). Such a dimension proves that the “span” was a geometric measure and not an anthropometric one; it was obtained by attaching an anthropometric measure such as a digit, measured by its width, to a coefficient. However, for land measures, certain spans were smaller, and the *vara* was therefore equal to two spans: in Tula, there was a division of land in order to reform the tax law, and “each Indian was given 100 *varas* in

length and 20 in width. Each one of these *varas* made two spans; this is the measure which the Indians use.” Standards of measure and length existed, and, to measure land, poles or cords were used, just as European surveyors did. Road measures also existed, which were used by travelers, soldiers, and merchants. These were the *cennecehuilli* and the *cennetlalolli*, which Spanish authors tended to translate as “leagues.”

Weights and Measures in Peru

Shigeo Iwata

Ancient Peru covered most of the Andes, where the Peruvian culture lasted for more than 10,000 years. Because most of the region was in the highlands, more than 3,000 m high, their metrology was slightly different from other civilizations. Also, they had no form of writing until 1532. For calculation and for recording metrological units decimally, they used *quipus*, spatial arrays of multicolored knotted cords. The names of the units and the values differed significantly depending on the period, the people, and the region.

Length

Peruvians used linear measurements that were related to human measurement patterns. Examples are listed in Table 1.

Peruvians chewed lime and *lipta* with coca leaves as a stimulant. They invented a measure called *cocada*, which measures how far one can walk while under the drug’s influence. This distance is 3 km on level ground or 2 km on an uphill slope when carrying a 45 kg load for 35–40 min in Pataz county.

A twelfth-century pre-Inca site in Puruchuco, located about 6 km from Lima, was recently restored. The linear measurements of each part of the structure showed that the average stature of men from head to toe was 1.701 m, while the height from the middle fingertip to one’s toe was 2.106 m. They used a geometrical design of proportions based on the golden section (1:1.618) between the sides of the rectangles.

Area

The Aymara called the area where they could raise one or two heads of cattle the *callapa*. *Tupu* was the Incan name for an area of cultivated

Weights and Measures in Peru, Table 1 Examples of Peruvian linear measurements

	Quechua	Aymara	Inca	Ratio	Metric system
Handbreadth		<i>ttkhlli</i>		0.051	8.5 cm

		<i>chuta (sayhua)</i>		10^4	16.8 km
			<i>guamanin</i>	10^5	168 km

land or pasture where a married couple could live. The Inca called the area, which was equal to 625 m² *hui*ri. This was the area a man could cultivate in 1 day. The Cuzco called the area equal to 282 m² of sweet potatoes or corn *papacancha*.

Volume

The Peruvians used a single hand-cupped *gowpen* to measure small portions of grain. They also used gourds, dried pumpkins, pots, and jars to measure things. The names of the units and the values are shown in Table 2.

The Quechua called a broad crate filled with coca or red pepper a *runcu*. One-half of

a *runcu* was called *checta runcu*, one-fourth was called *cutmu*, and one-eighth was called *sillcu*.

Mass

Because fewer weights have been discovered in the Peruvian region than in other civilizations, it has been difficult to estimate the mass standard accurately. We assume that the average mass of unit was 23.1 g. The notation was based on the decimal system. The maximum unit was assumed to be 23.1 kg, which is about 80 % of the maximum units from other civilizations, 27–30 kg in Egypt, Mesopotamia, Indus, and China. This is probably because of the low concentration of oxygen in the atmosphere in the Andean highlands.

Thirty-nine percent of the weights were made of stone, 32 % of iron, 24 % of lead, and 5 % were made of other nonferrous metals. One-third of the weights were globe-shaped; the others were conical, cylindrical, or in spindle and other irregular forms.

All types of scales, namely balance, steel-yard, bismar, and movable load, were

Weights and Measures in Peru, Table 2 Hand-cupped “gowpen” measure of the Peruvians

	Quechua	Aymara	Ratio	Metric system (cm ³)
Gowpen (double hand-cupped)	<i>poktoy</i>	<i>iuu</i>	0.043	300
		<i>laqui</i>	1.00	7,000
	<i>pokcha</i>	<i>hullu</i>	2.00	14,000

Weights and Measures in Peru, Fig. 1 Bismar (Adapted by the author from Uhle (1925), p. 335)

Weights and Measures in Peru, Fig. 2 Movable load scale (Adapted by the author from Rivet (1923), p. 535)

discovered in the northwest region of South America. The fulcrum was the cord-pivot type. Balance beams were made of wood, horn, and bone with humans, monkeys, birds, and geometrical patterns engraved on them. The two items supporting the load and weights were mostly nets, and partly pans of metals. The balance might have been invented by the ninth century (Figs. 1 and 2).

Miquel de Estete, who attended Francisco Pizarro, found a steelyard on the coast of Ecuador in 1531. The steelyard was graduated from the middle of the beam to the end, and had a bob-weight suspended from the arm. The steelyard was used to weigh gold and silver. The bismar was discovered at the market in Tarma, 170 km northeast of Lima. The total length was 27.8 cm, and the capacity was assumed to be 924 g. The movable load scale, called *wipe* in the actual place, was discovered in Huarochiri,

Weights and Measures in Peru, Fig. 3 Balance (From the Museo Amano)

90 km to the east of Lima. The scale was made of wood, and was used to weigh coca leaves (Fig. 3).

Weights and Measures in the Indus Valley

Shigeo Iwata

The golden era of the Indus civilization in ancient India extended from 2300 to 1750 BCE. This vast civilization had significant uniformity and standardization in its material culture, as reflected in its town planning, building construction, pottery, metallurgy, and system of weights and measures.

The prosperity of the Indus cities depended to a large extent on trade. Many raw materials were brought by land and sea routes from within and outside the Indus valley. Inland trade must have extended beyond the Baluchistan to Afghanistan route and the Iranian highlands on the one hand, and to the Punjab and Aravalli hills on the other. Overseas trade covered the Makran and Persian Gulf ports on the west and the Gujarat and Konkan ports, if not those of the Malabar coast in the south. The writing system has not yet been deciphered, and the names of their measuring units are still unknown.

Length

A unit of length, which corresponds to a fathom, was revealed in the process of analyzing the city plans of Lothal, Surkotada, Kalibangan, Dolavira, Harappa, and Mohenjo-daro. The mean value with standard deviation of the units used in these cities was 168 ± 1.1 cm.

The minimum division of graduation found in the segment of an ivory-made linear measure excavated in Lothal was 1.79 mm (that corresponds to 1/940 of a fathom), while that of the fragment of a shell-made one from Mohenjo-daro was 6.72 mm (1/250 of a fathom), and that of bronze-made one from Harapa was 9.33 mm (1/180 of a fathom).

Area and Volume

The use of area measures should have been quite common. There is, however, no piece of evidence that could be connected with an area measure. In the excavations carried out at various sites of the Indus civilization a variety of pots made of clay, and sometimes of metal, have been discovered. No systematic determinations of the volumes of pottery seem, however, to have been made.

Mass

The oldest known weight in the Indus measuring system was excavated from Dashli Tepe, south Turkmenia in Russia. This era dates back to the fifth millennium BCE. The other three weights belong to the fourth millennium BCE and were discovered in northern Iran. These weights belong to pre-Indus civilization. In the third millennium BCE the Indus measuring system was further developed in the ancient regions of Iran and Afghanistan.

A total of 558 weights were excavated from Mohenjo-daro, Harappa, and Chanhu-daro, not including defective weights. They did not find statistically significant differences between weights that were excavated from five different layers, each measuring about 1.5 m in depth. This was evidence that strong control existed for at least a 500-year period. The 13.7-g weight seems to be one of the units used in the Indus valley. The notation was based on the binary and decimal systems. Eighty-three percent of the weights which were excavated from the above three cities were cubic, and 68 % were made of chert.

Balance pans were made of copper, bronze, and ceramics. A bronze beam was found with the two pans in Mohenjo-daro. The fulcrum was the cord-pivot type (Fig. 1).

The measuring system used in the Indus valley was different from the Mesopotamian and Egyptian measuring systems, but the sensitivity of precision balances used in these regions is assumed to have been comparable. The weights

excavated from Taxila (sixth century BCE to seventh century AD) descend from the system of weights used in the Indus civilization (Fig. 2).

Weights and Measures of the Hebrews

Lionel Holland
Caesarea, Israel

Weights

The earliest Biblical reference to a unit of weight is in Genesis 23:16: “Abraham came to an agreement with him and weighed out. . . four hundred shekels (of silver) of the standard recognized by merchants.” Abraham was a new immigrant in Canaan. The *shekel* units which he used to weigh out the silver for Ephron the Hittite may have been those of his native Mesopotamia, with which he would have been most familiar.

The Mesopotamian shekel weighed about 8.3–8.5 g. Sixty shekels = 1 *maneh* (Greek: mna, mana. English translations of the Bible often render *maneh* as “pound”) of 497–508 g. Sixty *maneh* = 1 *kikar* (Greek, Talanton; English,

talent) of 29.8–30.5 kg. This system, which was originally Sumerian, in the fourth or third millennium BCE, was used with little change for thousands of years by the peoples of Mesopotamia; the terms SH-Q-L, M-N-H, and K-K-R are Semitic in origin and were first used by the Akkadians. Systems similar in structure, though varying in detail and in the absolute mass of the units, were used by most of the peoples of the Eastern Mediterranean, well into Roman Imperial times.

The term shekel is, in short, a generic one, and in this context could apply to any one of a number of units (including the Mesopotamian) in use in Canaan in the Bronze Age. Since the price of 400 shekels for the Cave of Machpelah was quoted by Ephron himself (Genesis 23:14), these may very well have been shekels of the Syrian standard (also called Ugaritic), weighing about 9.4 g. Weights on this standard were used throughout Canaan and northern Syria and are found at Bronze Age sites in the Aegean Sea, as far north as Troy. The standard also reached Egypt, where its unit became the *qedet*. Three thousand Syrian shekels made one *talent*.

Genesis 24:22 says: "...the man took a gold nose-ring weighing half a shekel, and two bracelets for her wrists weighing ten shekels ..." The Hebrew word rendered in English as "half a shekel" is *beka'*. The word means "half" and appears on certain Iron Age weights described below.

The next mention of units of weight in the Bible is in the Book of Exodus. Several hundred years have passed; the Children of Israel, now a numerous people, have received the Law at Mt. Sinai. This includes instructions for the payment of taxes and the performance of religious ritual, which call for clearly defined units of measurement. The first specifically Hebrew unit of weight is *shekel ha-kodesh*, which the King James version translates as "shekel of the sanctuary" and the New English Bible as "shekel by the sacred standard," "twenty *gerahs* to the shekel" (Exodus 30:13). This unit is referred to repeatedly (Exodus 30:24, 38:24–26; Leviticus 5:15, 27:25; etc.). Reference is now also made to *talents* of silver and gold: the *talent* weighed 3,000

shekels (Exodus 38:25, 26). There are no surviving artifacts of this period from which the absolute mass of these units might be inferred.

It should be stressed that the *shekel ha-kodesh* and its fractions were used by the Hebrews for religious purposes, but not necessarily in commerce. In the ancient world, as in medieval Europe, there were many weight systems in simultaneous use in international trade. Weights representing all the major systems of the ancient Near East are found at all important archeological sites in Israel and were obviously in use there. These systems are often linked by networks of interrelationships, with multiples of different units having a common mass and being used interchangeably.

The oldest extant weights bearing Hebrew inscriptions date from the period of the Kingdom of Judah (tenth to sixth centuries BCE). They are normally of limestone, dome-shaped with a flat bottom; a few bronze specimens exist. There are several types, all rare. The total number of known specimens of all groups is a few dozen. They are:

- *Necef*. Average mass about 9.8 g. The *necef* is not mentioned in the Bible. The name means "half": it may have originally been half of some more ancient unit. Scholars today identify the *necef* with the Canaanite/Syrian/Aegean unit already described. It is also equivalent to 1 Egyptian *qedet* and to four-fifths of the royal *shekel* of Judah (see below).
- *Beka'*. This word also means "half" (Genesis 24:22, see above). The mean mass of this group is about 6 g. The *beka'* is one-half of the "shekel of the king" first mentioned in II Samuel 14:26.
- *Pym* (Petrie: *peyem*). Mean mass about 7.8 g. The word appears once in the Bible (I Samuel 13:21): "The charge was two-thirds of a shekel (Hebrew: *pym*) for (sharpening) ploughshares and mattocks, and one-third (of a shekel) for sharpening the axes and setting the goads." The *pym* is two-thirds of the royal shekel.
- *Shekel*. Weights of this group are inscribed, not with a word, but a sign γ . Its meaning has been variously interpreted as being an official adjuster's mark, a symbol of the bag (*tsror*) in

which lump silver was often carried, and a stylized representation of the royal scarab emblem of the kings of Judah. Sir Flinders Petrie read it as a monogram composed of the Greek letters *chi* λ and *omicron* o and, on this basis, erroneously attributed these weights to a (supposed) system which he called Khoirine. The mean mass of the shekel, calculated from all known marked specimens, is about 11.4 g.

The shekel sign is accompanied by a mark indicating the denomination: 1, 2, 4, 8, 16, and 24. Since numbers of shekels are given in the Bible in multiples of 50, this binary multiplication seems illogical; it is explained by the fact that this shekel is equal in mass to one and a quarter Egyptian qedets. Hence, 4 shekels = 5 qedet, 8 shekels = 10 qedet, etc. The denomination marks on the shekel weights are, in fact (apart from simple strokes to indicate 1 and 2), Egyptian hieratic decimal numerals, the sign for 4 shekels meaning in Egyptian 5, that for 8 meaning 10, and so on. These weights thus could be conveniently used interchangeably to weigh either in shekels or qedets. In fact, it can be seen that all the units here described are closely related. The Canaanite/Syrian/Aegean maneh of about 940 g can be divided into either 80 royal shekels, 100 necef (or qedet), 120 pym, or 160 beka', providing simple arithmetical relationships between the systems prevalent in different regions.

The name "royal shekel" is confirmed by the existence of a two-shekel weight inscribed in Hebrew "L-M-L-KH" (of the king). A series of fractional weights also exists, both for the shekel and for the necef, showing that both were divided into 20 units (*gerah*). The denominations of these are also indicated by Egyptian hieratic numerals.

Scholars attribute most of these weights to some time near the end of the seventh century BCE, leading some of them to suggest that the religious reforms of Josiah (II Kings 22, 23; II Chronicles 34, 35) were accompanied by a reform of weights and measures. There is no

direct documentary evidence of this. In fact, biblical references are less than enlightening. Ezekiel, foreseeing the rebuilding of the Temple, orders that the maneh shall consist of "twenty, and twenty-five, and fifteen (i.e., 60) shekels." This is so inconsistent with other data that the translators of the New English Bible assume a misspelling in the Hebrew text and render *essrim* as "ten" (Ezekiel 45:10), giving 50 shekels to the maneh as before. After the Temple was rebuilt, the people of Israel pledged to pay an annual tax of one-third shekel, not one-half as in Moses' time (Nehemiah 10:32).

Nothing more is heard of the *shekel ha-kodesh*; it is last mentioned in Numbers 18:16. Yet the correct weight of the Temple tax was a subject of deep concern to the Jewish religious authorities; it is discussed at length in the Mishnah, the textbook of Jewish laws. By the first century BCE, it had been decided that all religious taxes should be paid in "shekels of the sacred standard, of the maneh of Tyre." The Tyrian shekel at that time weighed a little over 14 g and was famous for its purity of metal and uniformity of weight. No other coin would do. This is the reason why Jesus found so many money-changers in the Temple precinct (Matthew 21:12): Jewish pilgrims arriving from foreign parts and wishing to pay their dues needed Tyrian shekels in order to do so.

From AD 66 to 70, when Jerusalem was besieged by the Romans and Tyrian coin was no longer obtainable, the shekels struck throughout the siege by the embattled Jews (probably for religious use) were of the Tyrian standard.

The use of Hebrew weights and measures for secular commerce almost certainly ended with the fall of the Kingdom of Judah and the destruction of the Temple by Nebuchadnezzar in 586 BCE. There is no evidence from the successive periods of Persian, Hellenistic, and Roman domination of the Land of Israel (or from times of relative independence, under the Hasmonean and Herodian dynasties) of the use of any specially Jewish units. Rabbinical discussions of weights and measures usually center on attempts to define

Biblical units in terms of contemporary non-Jewish systems, in order to ensure the proper performance of the mitzvot (commandments).

Measures of Length and Area

The Hebrew unit of linear measure was the *ammah* or cubit – the length of a man’s forearm, from the elbow to the tip of the middle finger. Deuteronomy 3:11 actually uses the expression *le-ammat ish* – “by the forearm of an adult male.” The measurement of length by units based on parts of the human body is universal among ancient cultures.

The Bible mentions no unit greater than a cubit. *Kaneh ha-midah*, the surveyor’s measuring rod (or reed), was six cubits in length (Ezekiel 40:5). The measurements of the inner temple are given by Ezekiel as 500×500 *kaneh* (Ezekiel 42:16–20); the Authorized Version translates these as “reeds,” the New English Bible as “cubits.” Surveyor’s measurements of up to 25,000 cubits are on record (Ezekiel 45:1). Long distances are expressed in terms of a day’s journey, *derekh yom* (Genesis 30:35; Numbers 11:31; II Kings 3:9).

The Hebrews used two cubits, one a hand’s breadth (*tefah* or *tofah*) longer than the other (Ezekiel 40:5, 43:13). The longer cubit was used in the rebuilding of the Second Temple (Ezekiel 40–48) and also, presumably, in building the Temple of Solomon, since the dimensions quoted for the Holy of Holies and the Sanctuary are the same in both cases (20×20 cubits and 20×40 cubits, respectively: I Kings 6:14–28, Ezekiel 41:1–4).

The use of two cubits suggests an association with Egyptian linear measure. The greater (“Royal”) Egyptian cubit was of seven hands, each hand of four fingers (also four spans of seven fingers each). Its length of about 52.5 cm is attested by many surviving measuring rods and by records of the dimensions of surviving monuments. The lesser Egyptian cubit was of six hands.

The Biblical fractional units of length are the span (*zeret*, Exodus 28:16, 39:9; I Samuel 17:4), the hand (*tefah* or *tofah*, Exodus 25:25, 37:12; I Kings 7:26; II Chronicles 4:5), and the finger (*etzba*, Jeremiah 52:21). The only direct clue to the absolute value of the Hebrew cubit is the Siloam inscription (ca. 700 BCE) from which Conder estimates a value of 17.1 in. (43.4 cm); he warns, however, that this estimate may be in error by 10 % or more.

The Mishnah (second to third century AD) states that the greater cubit was of six hands, the lesser of five; the hand is of four fingers. Six hands of Egyptian dimensions would measure 45 cm. Most rabbinical estimates, however, are in the range 58–66 cm.

There are no specially named units of area in the Bible. Ezekiel, discussing the layout of rebuilt Jerusalem, speaks of “twenty-five thousand cubits square (*revi’it*)” (Ezekiel 48:20).

Measures of Cubic Capacity

...your bushel (Heb. *ephah*) and your gallon (Heb. *bath*) shall be honest. There shall be one standard for each, taking each as the tenth of a *homer*, and the *homer* shall have its fixed standard (Ezekiel 45:11).

Solid and liquid measures are thus given a common basis. The volumetric measures mentioned in the Bible are *ephah* (Leviticus 19:36; Deuteronomy 25:14 (“measure”); Judges 6:19; Ezekiel 45:24); *s’ah*, *seah* (Genesis 18:6; I Samuel 25:18; I Kings 18:32 (always “measure”)); *kab*, *cab* (II Kings 6:25); and *omer* (Exodus 17:36 – “An *omer* is one-tenth of an *ephah*”); these are always associated with solid measure. *Letekh* (Hosea 3:2 – AV, “a half *homer* of barley”; NEB, “a measure of wine”) is mentioned only once. *Homer* (Ezekiel 45:11, see above) and *kor*, *cor* (I Kings 4:22, 5:11) are associated with both solid and liquid measures. *Bath* (I Kings 7:26, 38; I Chronicles 2:10) and *log* (Leviticus 14:10, 12, 15, 21, 24) are associated with liquid measure. The relations between any

of these measures are only mentioned once or twice. The Mishnah gives a table relating some of them: 1 *ephah* = 3 *se'ah*; 1 *se'ah* = 6 *kab*; 1 *kab* = 4 *log*; 1 *log* = 6 eggs. The water displaced by 1 egg is about 55 ml (there are differing rabbinical views on the precise quantity), which would give the *log* a volume of 330 ml and the *ephah* and *bath* each about 24 l.

Attempts to establish mathematical relationships between ancient units of length, mass, and volume were popular a century ago, but today are not taken seriously. Reliance on post-Biblical authors such as Josephus Flavius is also risky: Josephus lived more than a thousand years after King Solomon and is more likely to have been concerned with giving his (mainly non-Jewish) reading public a notion of orders of magnitude than with achieving a maximum of mensural precision. Hebrew weights and measures will always remain a subject fraught with uncertainty, which will be dispelled only when archeologists are able to recover the actual instruments of measurement.

Weights and Measures: Animal-Shaped Weights of Burma

Donald Gear and Joan Gear

The royal animal-shaped weights of the Burmese Empires appear to be unique not only as a weight system, but also as one of the most important artifact series, especially in a country with but few durable artifacts. Their shape motifs are mythically leonine (lion-like), elephantine, anserine (goose-like), and gallinaceous (poultry-like). They symbolize Buddhist and pre-Buddhist beliefs, and the Burmese institution of monarchy and its continuity, dynastic, and imperial changes.

For the purpose of this account the Burmese empires comprise those regions of the Southeast Asian peninsula now known as Myanmar (Burma) and northern Thailand (Siam).

Buddhist art in India gave rise to the Burmese choices of animal motifs to use on the weights. The anserine weight, in a tenth century Indian style, apparently was chosen first during a period of Theravāda revival. However, the motifs were ancient even then, originating before the Burmese entered Burma. Shamanistic and animistic influences, both of the post-1000 BCE steppes and China, are also evident. Even more obvious is the use of Chinese models and execution for most of the style groups. Moreover, the decision to use Buddhist symbolic animals may also have been influenced by the enduring association of Indian and Chinese Mahāyāna Buddhists with commerce.

The mass units and scales reached Burma from India before the twelfth century AD, but India itself obtained them from Achaemenid Persia, which in turn, obtained them from Assyria and Babylonia. However, with the growth of Chinese trade in Southeast Asia from the thirteenth century onward and the adoption in Burma of Chinese mass standards, the Indian mass system was displaced. (A mass unit is defined here as that which was used in multiples to form weights

Weights and Measures: Animal-Shaped Weights of Burma, Fig. 1 Weights of different shapes (Photograph by the author)

mainly used for heavy trade goods and in fractions mainly for bullion or small amounts of other valuable items, the multiples and fractions together forming the mass scale).

A Burmese term often given to the animal-shaped weights is *shway arlay* (gold weights) which may have been derived from the expression *sri arlay* (king's weights). However, in the East the word gold has customarily been associated with royalty. Also, until the late eighteenth century the weights of Burma were mainly used on behalf of the king, who enjoyed monopolies in trade and was the chief import/export broker.

Of the three main weight shapes, the leonine and anserine were used throughout the empires, while those of elephant shapes were used only in north Siam. The first two shapes were still in use in 1970 along the more remote routes that pass from northeast Burma into Yunnan, north Siam, north Laos, and the Thai cantons of Vietnam.

Most commonly, the diameters and heights of the weights do not exceed about 70×120 mm. In shape they occur in three leonine- and seven bird-weight style groups which can be placed in stylistic sequence. A sequence in the elephant-shaped weight styles has not been identified with certainty (Fig. 1).

The leonine shape, called *to* (taw = "royal" in Burmese) is a stylized combination of the parts of

four animals. The lion of west and south Asia supplied the model for the open-mouth, bearded head and probably for the crouching torso. The horns were either bull-like or were adapted from the antlered muntjac deer of eastern and southern Asia. The tail of two of the styled groups is usually lion-like, but it is occasionally horse-like. With one exception, all the tails are characterized by the artificially raised tail base of the ancient Yunnanese horse. The legs and feet were modeled upon those of the elephant. All these animal representations are present on the abacus of the Asokan pillar at Sarnath.

The standing bird shapes of six of the bird style groups are in the form of a stylized Chinese mandarin drake (*aix galericulata*) having a knobbed crest and known as a *hintha* (Pali). The model for the squatting/brooding, gallinaceous style group has not been identified.

The elephant shapes are naturalistic. In Siam, the weights of elephant shape, known as *chang* in Thai, are difficult to separate from those figurines of similar shape intended for other purposes. The animal representations stand on usually pyramid-shaped bases which may be rectangular, octagonal, circular, or hexagonal.

Frequently, impressed signs 4–19 mm in size are found, usually on the front or right side of the base. In shape they may be script-like circular, square, bird- or feline-like or in patterns normally

Weights and Measures: Animal-Shaped Weights of Burma, Fig. 2 Weights of different sizes (Photograph by the author)

of 4, 5, 6, 8, and 9 rays, diverging from a central point. These also can be placed in sequence.

The weights are made of a metal alloy, the essential components being copper (50–80 %), lead (3–30 %) and tin (0–20 %). In some of the nineteenth century weights zinc may amount to as much as 35 %. The alloy, formally known as *ganza* (Tamil *kamsa*), was imported either in the form of broken vessels from Canton or as the coins known as *cash* (Sanskrit, *karsha*) from Yunnan.

The *kyat* was the mass unit of the *to* and *hintha* weights and varied with time from about 14 g in the fifteenth century to over 16 g in the eighteenth century. The 20 *kyat* (320 g) weights constitute about 50 % of all weights, while weights with a mass of about 250 *kyats* (3,750 g) amount to about 2 %. About one-half of the elephant weights weigh less than 45 g and 2 % have a mass greater than 130 g. The average mass unit of the upper part of the gallinaceous mass scale is about 11.2 g and that of the lower part is about 13.9 g. The average mass unit of the elephant-shaped weights is about 12.7 g (Fig. 2).

The essentially decimal mass scale of the *to* and *hintha* weights, based on the mass unit of one *kyat* is 1/8 (or 1/10); 1/4 (or 1/5); 1/2; 1; 2; 5; 10; 20; 50; 100; 250. The elephant-shaped weights occur on the following scale: 1/8; 1/4; 1/2; 1; 2; 5;

10; 20; 40; ?; 60. The gallinaceous scale, at about 37 g, separates into an upper binary scale (1; 2; 4; 8; (?); 32 and what may be a lower trinary scale, 1/9; 1/3; 1. Bengalese and Chinese mass scales of the period are similar in part.

Ninety-nine percent of the *to* and *hintha* weights fall within ± 12 % of the mean mass of a particular style group while about 51 % of them fall within ± 2 %. These variations lie in the making of the weights not in additions, subtractions, oxidation, nor wear. The accuracy of the elephant weights (and figurines) is less.

During the nineteenth century the weights were made at a village near the capital under the supervision of the Chief Minister. These standard weights were stored in the treasury and issued to officials in other towns. It was a criminal offense to use weights other than those made “at the palace”. Special sets of weights were kept for the purposes of comparison and the settling of disputes. Though only two nation-wide “standardizations” have been recorded, the earliest in the eleventh century, nevertheless it was the required duty of each new monarch, upon ascending the throne, to verify the weights.

Copies of animal-shaped weights, usually somewhat crude, are still made today in eastern Burma (Shan States) using techniques similar to those of thirteenth century AD and second

century BCE Burma and Yunnan. The weights were made by the lost-wax technique, using clay to surround the wax model and metal molds to shape the wax model. The high-melting point wax used was produced in Yunnan by an insect.

Among the goods imported from India which may have required weighing were opium, indigo, and mercury. From Yunnan came gold leaf, silver ingots, copper-alloy, cash, salt, white insect wax, cinnabar, and tea. Burma exported gems, including pearls and coral, costly medicines, musk camphor, gums, resins, waxes, ivory, rhinoceros horn, and rare woods. Considerable trade would have been done with other Southeast Asian states, e.g., tin from Malaya and Laos, arsenic, lead, and silver from the Shan States, zinc from Laos.

Seeds and a Chinese type of equal-arm balance were used for the weighing of small highly valuable articles and the steelyard or datchin for large masses. For moderately valuable articles, e.g., foreign silver coins and ingots, the animal-shaped weights would have been used.

Until after the middle of the eighteenth century ordinary village commerce was conducted by barter, counting, purchase with cowries, and by measurement of volume or length. Weights were rarely necessary. However, from the last quarter of the eighteenth century onward, it was the ordinary Burman, rather than the king's officers, who made use of the weights, mainly to weigh currency ingots. This change was caused by the Burmese wars of the time. These resulted in the cessation of the supplies of copper alloy and cowries, led to the Burmese capture of the large lead and silver mines of the Shan States and so to the copying of the Chinese practice of using chopped lead as a low value currency. As a result of the increased need for weights to weigh the abundance of lead and silver ingots, there was a flood of copies from the formerly Burmese north Siam region, now occupied by south Siam (Ayuthya). This new domination also led to the replacement or adjustment of the animal-shaped weights to agree with those of south Siam.

Each of the weight shapes together with its base, and each of the parts of the weights, was intended to convey a particular meaning. The meanings had to be understood by illiterate

speakers of many different languages. Though they were intended to be understood primarily by animists and Buddhists, they would also have been understood by Confucianists, Daoists, and others. Characteristic of animist/Buddhist Southeast Asia (though originating much further away in space and time) was the belief in the earthly, semidivine king. This is what the *to* weight was intended to symbolize. It combined the physical characteristics of a potential Buddha (*bodhisattva*) and a universal monarch (*cakravartin*). These, in turn conveyed the idea of secular power both to animist and Buddhist, being associated with earth, fertility, and healing, with legitimacy of rule and righteousness of conquest (a prerogative of a universal monarch). New styles of *to* weights were issued only at the times of the "righteous conquests" of a Burmese king, usually at the beginning of a dynasty with the accompanying empire-building.

The *hintha* weight symbolizes, among other things, the heavenly perfection and purity of the Buddhist faith, especially that of the Theravāda belief characteristic of Burma and Siam.

The association of feline and anserine representations for symbolic purposes has an origin more remote than Buddhism. The lion-duck association is present on some Asokan pillars. Lion-shaped weights were in use in Assyria about 1500 BCE and duck-shaped weights in Sumeria and Babylonia.

Concerning the elephant weights the kings of Burma and Siam (Ayuthya) were the incarnations of Indra, the chief of the gods, who was ancient before Hinduism, and who rode on an elephant. Thus, one reason (among several) for the choice of the elephant was to symbolize these kings.

The most generally useful of the techniques for establishing the chronological sequence of the weights were the style and sign sequences; the relation of the *to* weight styles, through their symbolism, to the dates of the dynastic changes and territorial expansions; the sequence of increase in the average unit mass of each style group; the dates of the unit masses obtained from the weighings recorded by many European traders from AD 1515, and their relation to the average unit masses of the style groups.

Wells in China

Jiu Jimmy Jiao

University of Hong Kong, Hong Kong, China

Wells played an important role in early human settlements and are an important indicator of civilization. After the invention of wells, primitive societies could use groundwater to serve human purposes and were no longer confined to areas with convenient surface water (Jiao, 2007). A well was usually a gathering place of a village or town. In fact, the word marketplace or *Shi jing* in ancient Chinese literature literally means *market* and *well*. The market originated from a well site because people got together at wells to draw water while selling their goods (Du & Koenig, 2012).

Digging a hole underground to obtain drinking water is a basic instinct even for some animals such as elephants, but only humans can construct a well with a permanent structure. The first Chinese character of the well was found in the inscriptions on oracle bones in the Shang dynasty (1555–1059 BC). There are legends in ancient

Chinese history records which gave credit to two men, Bo Yi (about 2200 BC) and the Yellow Emperor (2698–2650 BC), for inventing wells, while the credit for other inventions such as paper and Chinese characters was given to only one individual. This suggests that well construction might have been practiced in different tribes independently in prehistorical China. *I Ching*, or *Book of Changes*, probably published around or even before 1000 BC, stated that “well water is clean and cool, and can be drunk.” In *Yingzao Fashi*, or *Treatise on Architectural Methods*, published in 1103 AD, the author Li Jie described how to build various wellheads.

A typical modern well may have three components: well body or shaft below the ground surface, wellhead above the ground surface, and the superstructure above the wellhead. The construction of the well body is the most complicated part. It involves excavation, a structure to support the wall, and construction of a well screen and filter below or/and around the well screen. A primitive well may be only a hole in the bare soil but a sophisticated one may have all the components, including a well-constructed shaft.

Prehistorical Wells in China (Before 2100 BC)

A well is a common structure in residential areas after early humans transferred from nomadic lives to lives of settlement, because wells have been frequently unearthed by archeological excavation at many Neolithic culture sites in China. Various human-made depressions such as ash pits, storage pits, kilns, and house foundations may exist in an archeological site. A hole is identified to be a well usually on the basis of some of the following features: a bottom deep enough to reach the then water table (which may be marked by a brown-like horizontal strip), straight or nearly straight walls, footsteps cut into the wall for easy access, relic water vessels, mud or sandy sediments formed underwater exist at the bottom, and well frames.

Wells in China, Fig. 1 Distribution of prehistorical wells in China unearthed before about 2011. The well sites are indicated by green circles. The background shows the

provinces (black circles) and direct-controlled municipalities (stars). The reference of each numbered well site can be found in Cui (2011)

When a well is found in an archeological excavation site in China, the well is studied as one of the many archeological items. So far there is no study focusing on the well itself to understand its paleo-hydrogeological implication. The age of a well and its operation period are usually estimated indirectly from other archeological items or the pottery fragments deposited inside the well.

In China, the wells in prehistory unearthed so far are mainly located in two regions: the coastal and central plains of the Yellow River and the coastal plain of the Yangtze River (Cui, 2011; Fig. 1).

Wells in the Yangtze River Plain

The prehistorical sites with wells in the coastal plain of the Yangtze River cover periods ranging

from the Majiabang culture (5000–3000 BC) to the Liangzhu culture (3400–2250 BC). In addition to primitive wells in bare soil, wells supported by hewn logs, wood planks, and weaves of reeds and bamboos or willows are also found. Most of the wells in the coastal plain of the Yangtze River are shallow and less than 3-m deep, probably suggesting a low water table.

Among all the wells, the one found in the Hemudu Neolithic Ruins (5000–4500 BC) is probably the most extensively documented (site 1 in Fig. 1). The well was built approximately 5,600 years ago (Jiao, 2007; Yang, 1987; Fig. 2). The well site contains over 200 wooden components and can be divided into inner and outer parts. The outer part consists of 28 piles around a pond. The inner part, the wooden well itself, lies in the middle of the pond. The walls of the well

Wells in China, Fig. 2 (a) The wooden well at the Hemudu site under excavation, (b) artistic impression of the well with a shelter (Jiao, 2007; Yang, 1987)

were lined with close-set timber piles reinforced by a square wooden frame. The 28 piles in the outer part of the site may have been part of a shelter for the well. The well is believed to have been developed from a natural pond. On the basis of the relic wooden piles around the pond, the orientation of three relic piles inside the well and the pond, and radially distributed small logs and the reed mat shreds, the Hemudu well is speculated to have a shelter (Fig. 2b). If this is true, this may indicate that the people of the Hemudu culture were concerned with water quality and the protection of their water source.

Wells of other construction types are also found. For example, a wooden well found at a culture ruin at Xingang Village, Jiashan County (site 21), belongs to the late Liangzhu culture (3400–2250 BC) (Cui, 2011). The wall of the well consists of two wood planks with a thickness of 5 cm and a length of 1.63 m. The inner diameter of the well is 45 to 63 cm. The planks are from a single tree, which was cut into two halves, with the wood inside being removed. The two pieces are connected by four wood bars which are fixed with the planks by mortise and tenon structure. Below the bottom of the wood is a 10-cm-thick layer of the shells of *Corbicula fluminea*, serving as a filter for the well. At another well site at Guangfulin ruins (site 22), which belongs to the late Liangzhu culture, the well has a diameter of 2.4–2.5 m near the ground surface but it narrows down to 0.3–0.5 at the

bottom. It has a depth of 3.1 m. At the bottom of the well is a box of bamboo plait with a height of 1.1 m. This structure of bamboo plait functions like a well screen which can support the wall of the well and also behaves as a filter to the groundwater. Some culture sites (e.g., site 5) have wells with reed mats near the bottom of the well which are supported by wooden piles.

Wells in Yellow River Plain

Compared to the Yangtze River plain, the culture ruins with wells in the Yellow River catchment are scattered widely in both the central and coastal river plains. Most of the wells are less sophisticated in construction but deeper, suggesting that the water table was typically lower. The prehistorical wells in the Yellow River plain so far unearthed dated as early as the Beixin culture (5300–4100 BC). The number of wells started to increase in the Dawenkou culture (4100–2600 BC) and became quite popular in the Longshan culture (3000–2000 BC). Most wells are simply vertical holes underground without well frames. The depth of the wells varies but usually is greater than 2 m in the early culture periods. It increases toward the late Neolithic cultures and can be over 4 m in the late Longshan culture. The shapes of the wells can be square, rectangular, round, or oval, but are dominated by square and circular at the late stage.

The wells in the central plain of the Yellow River largely belong to the Longshan culture.

Wells in China, Fig. 3 Wooden well in Baiyin ruin in late Longshan culture (Cui 2011)

There are wells in bare soil but also many wells enforced by wooden frames. Most of the wells are located in the residential areas, suggesting that they were for domestic use, but there are also two wells located near kilns, suggesting that they were for making ceramic products. The most impressive well is the one unearthed in the Baiyin culture site (2590–2100) (site 33) which belongs to the late Longshan culture. The well is square shaped, but with rounded corners (Fig. 3). The well dimension is 5.8 by 3.6 m near the surface but progressively smaller toward the bottom with a dimension of 1.2 by 1.1 m. The depth is 11 m. The wall is supported by 46 layers of hewn logs which are connected by mortise and tenon joints. At the bottom of the well, there is a layer of ceramic fragments overlying the original silty yellowish soil (Cui, 2011; Fig. 1).

Wells After Prehistory

The use of wells in ancient China (2852–1600 BC), including the dynasties of Xia (2100–1600 BC), Shang (1600–1046 BC), and Zhou (1045–256 BC), was very common (Du & Koenig, 2012). In the late Zhou dynasty, wells were very popular and the drilling technology was also significantly improved. Various materials such as ceramic rings, pottery clay, bricks, rocks, and hollowed trunks were commonly used to construct the underground part of wells, as observed at many archeological sites. However, the superstructure of a well was usually destroyed.

In the early stage of imperial China (221 BC to 1911 AD), a well became a household item of almost every family, especially in the north part of China. This is indicated by the well models widely unearthed in tombs in Han dynasty (206 BC to 220 AD) (Jiao, 2008). During this period, it was a common practice for the family to bury a dead person, together with some *mingqi*, or spirit wares, to honor their ancestor and make his spirit happy on the journey to paradise. A very popular *mingqi* in the Han dynasty is a miniature of well models, symbolic for water for the ancestor to drink. Such a well model gives us a vivid picture about the wellhead and the superstructure constructed in old China.

Description of various well *mingqi* can be found in Jiao (2008). While most of the *mingqi* are clay models, Fig. 4 shows a bronze model of a wellhead. The model has an elaborate base. The square wellhead sits on a pyramid-shaped platform with a trough between the sloping sides and the outer rim of the square base. Spilled water from the bucket could be easily drained to the trough. The appearance of the wellhead indicates that the original well was made of wood. The superstructure supports a winch or pulley that would hoist the bucket. Such a robust pulley system suggests that the water level may have been fairly deep. This model indicates that the construction of a well was very mature at least in the Han dynasty.

Most of the well models unearthed are mixed with other domestic items such as models of

Wells in China, Fig. 4 A model of bronze wellhead with pulley and bucket unearthed from a tomb of Eastern Han dynasty (AD 25–220 AD) in Shandong Province. The model is 49.5 cm high and 48 cm wide (*square base*) and is a collection of Shandong Provincial Museum (<http://www.asianart.com/exhibitions/shandong/14.html>)

kitchens and toilets, suggesting that these wells were for domestic purposes. There are also some ceramic models of wells which suggest that wells may have been used for irrigation or to extinguish fire (Jiao, 2008).

While large-diameter shallow water wells have been used since ancient China, driven by the salt industry, salt wells started to be built in the Western Jin dynasty (AD 265–316 AD) (Zhou, Zwahlen, & Wang, 2011). Almost 1,000 years ago, people in Zigong, Sichuan Province, were able to drill small-diameter boreholes 100-m deep using cable drilling techniques to pump water from deep brine aquifers to produce salt (Vogel, 1993). This technique was invented between 1041 AD and 1048 AD in the Song dynasty. To lift brine from the well, workers used a bamboo tube suspended from a rope. Today deep drilling is regarded as one of ancient China's greatest innovations, comparable to their invention of paper, printing, gunpowder, and compasses. Xinhai Well in Zigong, which reaches a depth of 1 km, was the deepest in the world when it was drilled in 1835. This well is

Wells in China, Fig. 5 A worker is demonstrating how to pump brine water from a deep well in Daying Country, Sichuan Province. The well is located at the *left-bottom corner* (http://www.sc.xinhuanet.com/content/2007-11/22/content_11744433.htm).

still operational and is a tourist attraction in Zigong. Figure 5 shows such a well in Daying Country, Sichuan Province. It is also called a bamboo well because all the major materials associated with the well, including the well bore, the rope, and the water containers, are made of bamboo, a widely available local plant.

Western Dominance

Michael Adas

Rutgers, The State University of New Jersey,
Piscataway, NJ, USA

Scientific curiosity was a major motive behind Western overseas expansion from the fifteenth century onward and technological innovations, particularly in shipbuilding, navigational instruments, and firearms, made that expansion possible. But early European explorers and conquistadors did not rely heavily on evidence of scientific or technological achievements as gauges of the worth of the peoples they encountered or as explanations for their growing dominance in the Americas and maritime Africa and Asia. In encounters with the great centers of civilization in Africa and Asia, European superiority in these endeavors was highly selective, marginal, or in many areas nonexistent. In fact, travelers to China and the Indian subcontinent in the early centuries of expansion were as likely to dwell on the technological deficiencies of the West, when compared to these great civilizations, as to boast of European advantages. As in India, China, and Japan, the Europeans were able to make little headway into the heartlands of the Islamic world in this era. That standoff and the fact that they had borrowed so heavily from the scientific learning and technology of Muslim cultures in the centuries of Europe's emergence as a global force, rendered it unlikely that material standards would supplant the long contested religious differences that the Europeans had employed to set themselves off from and above the followers of Islam.

In Africa, disease and geographical barriers and the power of coastal kingdoms prevented the Europeans from translating their technological edge into significant conquests. Failure to move into the African interior also meant that the Europeans had only the vaguest notions about African epistemologies or understandings of the natural world, which were usually dismissed as superstition or fetishism. In sharp contrast to their experience in Africa, European invaders encountered few disease barriers in the Americas. In fact, diseases from smallpox to the measles became powerful allies of the Spanish conquistadors in their assaults on the heavily populated and highly advanced civilizations of Mesoamerica and the Andean highlands. The long isolation of the Amerindian peoples from the Afroeurasian people and cultures left them highly vulnerable to both the microbes borne and the Iron-Age technology wielded by the European invaders. Nonetheless, the Spanish tended to attribute their startling successes in battle against seemingly overwhelming numbers of Aztec or Inca adversaries and the rapid conquests that followed to supernatural forces and to the superiority of their militant brand of Christianity over the "heathen" faiths of the indigenous inhabitants of the "New" World.

Lacking in-depth knowledge of the epistemologies and scientific learning of most of the peoples they encountered in the early centuries of overseas expansion and often enjoying only very selective (but at times critical) technological advantages over them, European explorers, missionaries, and Crown or Company officials were unlikely to rely on material standards to judge the level of development attained by other cultures or to compare overseas civilizations to Europe itself. Until at least the end of the seventeenth century, religious beliefs, or the Europeans' certitude that they possessed vastly superior understandings of the transcendent world, predominated as the gauge by which other cultures and peoples were assessed and ranked. Additional cultural variables, such as the position and treatment of women, were frequently cited as evidence of advancement or savagery; and physical features, especially skin color, were

sometimes emphasized in attempts to distinguish and rank the peoples encountered overseas.

Scientific and technological gauges of past attainments and present abilities remained peripheral to most evaluations of the peoples and cultures that the Europeans encountered as they expanded across the globe. None the less, signs of material advancement – the existence of large cities, sophisticated techniques of fortress construction, or evidence of complex scientific instruments – were often noted and even cited to support arguments regarding the level of development achieved by different peoples. In two areas in particular, in the perception and measurement of time and in perspectives on space associated with artistic and mathematical advances of the Italian Renaissance, European overseas observers began to see a clear divide between the West and all other civilizations and cultures. In addition, as early as the sixteenth century, European commentators began to rank African cultures beneath those of Asia and the Americas, not so much because of skin color or other physical features, as has often been argued, but due to what was perceived as a markedly lower level of material culture in Africa than that found by European travelers and traders in India, China, or central Mexico.

Although ideologies justifying overseas expansion and the domination of non-European peoples from the fourteenth to the early eighteenth century were rooted in religious belief and were generally culture – rather than racially – oriented, material accomplishment, including the assumed capacity for invention and scientific thinking, was increasingly associated with racist defenses of the enslavement of Africans. Defenders of the slave trade sought to counter the abolitionists' objections with often lurid descriptions of the alleged savagery of African life and the debased level of African material culture. Along with skin color and other physical differences, racist writers, such as Samuel Estwick and Dominique Lamiral, emphasized material backwardness and ignorance of the workings of the natural world as proof of the subhuman nature of Africans that justified their subjugation as slaves.

By the last decades of the eighteenth century, this rather broad association between racial ideology, material culture, and the defense of slavery was refined and enhanced by the rise of racist theories allegedly grounded in scientific experimentation and reasoning. Physicians and ethnologists devised a variety of measurements – from skull size and shape to genital configurations – in efforts to prove that there were innate physical, mental, and moral differences between human racial groups. The fact that the measurements reflected a priori assumptions and were based on small and suspect samples, and that even the racial categories themselves were hotly contested, did not prevent “scientific” racism from winning widespread support from European scientists, social commentators, and politicians throughout the nineteenth century. The tenets of scientific racism were popularized among the middle and working classes by practitioners of phrenology, whose booths could be found at county fairs and on the promenades of seaside resort towns, and by the pulp press, where allegedly scientific proofs of European racial superiority were linked to social evolutionist arguments for imperialist expansion.

By the first decades of the nineteenth century, scientific and technological gauges of human achievement and worth were clearly in the ascendant. Earlier measures of the level of development achieved by different cultures continued to be cited. Religious belief, for example, remained of paramount importance to missionaries active in overseas lands. But even missionaries increasingly linked Europe's advances in the sciences and invention to the rhetoric of Christian proselytization. Ignoring past and contemporary tensions between science and religion in Europe itself, prominent missionaries, such as the Abbé Boilat and David Livingstone, argued that Christian culture had been particularly receptive to scientific investigation and technological innovation, and that conversion to Christianity would promote the scientific and material development of colonized peoples. The growing numbers of ethnologists and professionally trained anthropologists, who found in the colonies relatively safe and fertile environments for their

research, also privileged nonscientific or non-technological standards, such as modes of political organization or gender relations, in assessing the level of development attained by African, Asian, Amerindian, and Pacific Island peoples. But evidence of material culture was increasingly linked to societal advance, and indigenous “superstitions,” or at best magical beliefs, contrasted with the scientific mindset that was seen as typical of the educated West.

A number of factors account for the dominance of material standards, particularly those linked to science and technological innovation, in nineteenth-century ideologies of European global hegemony. Most critically, the transformations wrought by industrialization from the middle of the eighteenth century in England and somewhat later in Belgium, Germany, France, and Italy made the gap in scientific and technological capacity and material development between western Europe and non-Western societies increasingly apparent to European and non-European observers alike. Maxim guns, steamboats, and railway lines carried elements of Europe’s industrialization to colonized areas, and champions of imperialist expansion reasoned that these wonders could not help but impress subjugated peoples with the unprecedented degree to which European societies had advanced over their own. Not only did European superiority in science and technology seem obvious, but also it could be empirically tested in ways that claims of higher religious understanding or moral probity could not. Europeans had vastly more firepower, could produce incomparably greater quantities of goods much more rapidly, and could move both these products and themselves about the globe with much greater speed and comfort than any other people, including the once highly touted Chinese. In an age when what were held to be scientific proofs were authoritative, attainments that could be measured statistically were viewed as the most reliable gauges of human ability and social development. Mechanical principles and mathematical propositions could be tested; cast iron or steel bridge spans could be compared for size and strength with the stone or wooden structures of

non-Western societies; and human skulls could be quantified in seemingly infinite ways to assess the highly variable mental capacity of the “races of man.”

The preeminence gained in the nineteenth century by scientific and technological standards of human worth and ability not only bolstered proponents of theories of European racial supremacy, but it also proved vital to various formulations of the civilizing mission ideology that both inspired and rationalized European imperialist expansion from the early 1800s to 1914. Chauvinistic politicians in the metropolises and imperial proconsuls in the colonies increasingly stressed the importance of the diffusion of Western science and technology to what they viewed as the benighted peoples and backward lands that had come under European control. Proponents of the civilizing mission confidently predicted that the world would be remade in the image of industrializing Europe. Given Europe’s material advancement, it was seen as appropriate that Europe and North America serve as the sources of capital, both machine and financial; of entrepreneurial, scientific, and managerial expertise; and of manufactured goods for the rest of the globe. In this view, the non-Western world, including both areas that had been formally colonized and those that had come under the informal sway of the Great Powers, were best suited to provide abundant and cheap land, labor, and raw materials that were required to fuel the industrial economies of Europe and North America.

According to the “improvers” or nonracist advocates of the civilizing mission, the spread of Western education among colonized peoples – emphasizing the inculcation of at least rudimentary Western scientific learning and technological skills – would provide the critical means by which the material level of non-Western societies would gradually be raised. Though they approved of the diffusion of essential Western technology to overseas areas under the paternalist supervision of European colonizers, racist apologists for imperialism had little faith in the ability of subjugated peoples to master the sciences or engineering of the West.

Thus, they envisioned the period of European "tutelage" extending for centuries, if not indefinitely, into the future.

The non-Western peoples who were the targets of the European colonial enterprise were very often awed and overwhelmed by their initial encounters with the science and technology of the industrializing West. Whether they were indigenous leaders resisting the growing encroachments of European forces or scribes and merchants who allied themselves with the invaders, the colonized could not help but be impressed with the clear and increasing advantages in power that the Europeans gained through their superior capacity to tap the resources of the natural world, to produce material goods, and to devise more deadly weapons. As surveys taken as late as the post-World War II era, such as those which form the basis for G. Jahoda's *White Man*, the science and technology of the colonizers gave them an aura of magical power among the colonized masses in many areas. Though Western-educated Africans, Asians, or Polynesians were likely to scoff at such expressions of popular admiration, most came to accept that Western science and technology were not only on the whole superior to their own but essential for the future "development" of societies they hoped someday to rule. Therefore, nationalist critiques of imperial domination often deplored the fact that colonialism had severely constricted the flow of science and technology from the West to dominated areas, and demanded that technical education and scientific facilities for indigenous peoples be expanded and improved.

By the last decades of the nineteenth century, however, a number of influential African, Asian, and Caribbean thinkers were mounting cogent challenges both to notions of European racial superiority based on evidence of scientific and technological achievement and to the advisability of the wholesale transformation of non-Western cultures and societies along Western, industrial lines. Much of this resistance to the hegemonic ideologies of the Western colonizers focused on efforts to reassert and revitalize indigenous epistemologies, modes of social organization, and approaches to the natural world. Thinkers such

as Vivekananda and Aurobindo Ghosh contrasted an Indian spiritualism with the deadening abstractions of Western materialism. African writers, such as the Caribbean-born Edward Blyden, deplored the devastating impact of the Atlantic slave trade on African cultures and celebrated the Africans' strong sense of community, reverence for and care of the elderly, and sophisticated artistic creations.

Ironically, these defenses of colonized cultures were buttressed by contemporary European anthropological studies, usually carried out under the auspices of colonial administrations; by the intense interest in "Oriental" religions fashionable among European intellectuals in the decades before World War I; and by the "discovery" of the abstract power of African masks and other forms of "primitive" artistic expression by Picasso, Derain, Matisse, and other avant-garde artists in the early 1900s. Inadvertently, however, the works of these first generations of Indian and African critics of European hegemonic ideologies often validated the very materialistic standards they sought to contest. For example, Indian thinkers, particularly Vivekananda, repeatedly stressed the scientific accomplishments of India's ancient civilizations, while African and West Indian writers, most notably Anetor Firmin, claimed Egypt, with its impressive engineering and architectural feats, as a civilization that black Africans had done much to build.

With the coming of the First World War, non-Western critics of what had been characterized as the excessively rationalistic, impersonal, and materialistic West found numerous, and highly vocal, European intellectual allies. The horrific trench slaughter on the Western Front and the multitude of ways that Western scientific knowledge and experimentation were harnessed to the war effort as a whole raised profound doubts for noted thinkers, such as Paul Valéry, Sigmund Freud, and Georges Duhamel, about the long-assumed progressive nature of Western science and technology.

After such a savage and suicidal war, the tenets of the civilizing mission rang hollow, and "scientific" racist thought came under increasing assault in both western Europe and the United

States. Collaboration with indigenous elites was increasingly stressed in the governance of the colonies, and a rhetoric of science and technology as agents of development through cooperation with indigenous peoples permeated colonial policy making.

European doubts about the directions taken by the industrial West and its global hegemony gave new impetus to African, Asian, and Caribbean critiques of European global hegemony. René Maran's *Prix Goncourt*-winning novel, *Batouala*, mocked the pretensions of racial superiority held by European colonizers, and idealized village life in French West Africa. The poets of the *négritude* movement, most powerfully L. S. Senghor and Aimé Césaire, mourned the suffering and destruction wrought by European science and technology in Africa and the lands of the slave diaspora, and inverted racist epithets by exulting blackness, intuition, affinity for the natural world, and indifference to inventiveness. Aurobindo Ghosh and Rabindranath Tagore viewed the war as the fulfillment of earlier Indian prophecies of a coming cataclysm in the aggressive and materialist West, and proof of importance of India's spiritual mission in the modern age. Mohandas Gandhi also cited the senseless violence and colossal destructiveness of the war in support of his sweeping assaults on industrial society. In the decades after the war, he sought to formulate for India (and implicitly for other colonized areas) a community-centered, low tech, and conservationist alternative to industrialized society as it had developed in the West. In this same period, Gandhi also worked out a strategy for confrontational but nonviolent protest that repeatedly proved an effective antidote to the advanced technologies of repression employed by Western overlords in the decades of decolonization from the 1920s onward.

Though battered and under assault, the scientific and technological underpinnings of ideologies of Western dominance survived the crisis of two global wars and the powerful critiques of Gandhi and the *négritude* writers largely due to the emergence of the United States as the global power from the 1920s onward. Entering the First World War late and just when new technologies

had restored a war of motion and decision, Americans continued their long-standing infatuation with science and technology after the conflict. Faith in the essentially progressive nature and beneficence of science and technology informed the development (later called modernization) theory that came to dominate both American thinking on colonial issues and that of the European and Japanese imperialist rivals of the United States. After World War II, America's chief rival, the Soviet Union, also championed a rhetoric of development that privileged science and large-scale industrialization. With modernization theory (in a number of capitalist and socialist versions) in the ascendant, non-Western alternatives to social development and economic well-being, such as that formulated by Mohandas Gandhi, were marginalized or openly spurned by the Western-educated elites that governed the new states that emerged from the collapsing colonial empires. Though alternative approaches have gained significant support in some of these new nations, most notably India and Tanzania, international agencies and Western and non-Western planners continue to rely upon modernization schemes, based overwhelmingly on Western precedents, to solve the problems of poverty and growing wealth differentials and the demographic and environmental dilemmas that have been building on a global basis for centuries.

Windpower

Richard L. Hills

There is little doubt that the first practical use of the wind as an energy source other than as the motive power for sailing ships occurred in the East. Those of Persia were probably the first but precisely when is uncertain. According to a story of al-ṭabarī, writing around AD 850, and later writers, the second orthodox Caliph, Umar ibn al-Khaṭṭāb, was murdered in AD 644 by a captured Persian technician, Abū Lu'lu'a, who claimed to be able to construct mills driven by the power of the wind and was bitter about the taxes he had to pay. This early date cannot be confirmed but Arabic geographers of the tenth century all confirm the existence of windmills in the region of Seistan in north eastern Iran. For example, al-Mas'ūdī around AD 950 wrote of the wind driving mills and raising water from streams.

Nothing has survived to show how such mills pumped water but later drawings of one type of windmill suggest that it could have been derived

from horizontal corn-grinding watermills. In the lower part of such watermills, the water fell down a chute and struck blades placed radially around a vertical shaft. The top of the shaft passed into a higher room and carried the upper millstone and so rotated it above the bedstone which was set on a floor in the middle of the mill. When developed into a windmill, the wind rotor was situated in the bottom of the mill. The building was constructed with four “loop holes” to direct the wind on to the blades from whichever quarter the wind might be coming. There might be eight or ten blades, and the wind was directed by the loop holes onto one side of the rotor. In this way the sails were pushed round on that side away from the direction of the wind while those advancing into the wind on the other side were shielded by the walls around the loop holes. The grinding stones were placed in an upper room with the upper stone turned by an extension of the rotor shaft in the “underdrift” manner. None of these mills has survived.

The type which may still be in use today had the grinding stones situated in a room below the rotor with the sails above. This necessitated a change to the “overdrift” method of driving the stones where the spindle passed down through the bedstone to a bearing underneath, which had to support the weight of both the upper stone and the sails. It was possible to disconnect the driving shaft at the place where it was connected to the upper stone at the “rynd” to allow for the stones being separated for dressing. The layout for grinding was similar to other corn mills with a hopper mounted on the wall from which the grain was fed into the central hole of the upper stone through a chute or shoe while the flour was passed out around the circumference of the stones.

The advantage of this second layout was that the rotors with the sails could be greatly enlarged. Mills near Seistan and on the borders of Iran and Afghanistan might have rotors approximately 5 m (16.4 ft) high by 3 m (9.8 ft) in diameter. There could be six or eight sails which had wooden framing that was interlaced with straw or covered with wooden boards. The upper parts of these mills were built with one wall that directed the wind on to one side of the rotor

while another wall shielded the other half. Sometimes matting screens were erected to help channel the winds to the sails. There were no brakes, but more screens might be placed across the slots between the walls to regulate the wind reaching the sails; to secure the mill when out of use, the rotor and upper millstone were lowered to rest on the bedstone. A wind speed of 22.40 m s^{-1} (50 mph) was needed to drive these mills at only 30 rpm. Such a mill, working with intermittent wind for about 4 months of the year, would grind enough flour for about 15 families. Seistan was known as the land of the winds and between mid-June to mid-October the wind regularly blew from the north for a period of 120 days. The mills were built in line to face these winds and the famous example at Neh had a long row of 75 mills.

Because these horizontal mills needed such strong and regular winds to power them, they did not spread in this form much beyond the borders of Iran and Afghanistan. They were invented earlier than the Western vertical type but it is doubtful whether there is any connection between the two. Those in the West, which have been described as the “full admission, axial flow type,” first appeared around AD 1150 possibly either in the southeast of England, the northwest of France, or Flanders. However these Persian mills were probably the source of the later Chinese mills and possibly the Tibetan wind-powered prayer wheels.

The wind-powered Tibetan prayer wheels were not surrounded by elaborate buildings to guide the wind onto the rotors. The most common form had a vertical axle with horizontal spokes at its top, on the ends of which were fixed sails shaped like cups so that they caught the wind on one side of the rotor, but were smoothed or curved to present less resistance on the other. The wind would be caught in the concave part of the cup, or a curved sheet, during half the circle to turn the rotor, while in the other half, the convex or streamlined side would be advancing into the wind and so present less resistance. Power output was minimal but was sufficient to turn the prayer wheels which was the only use to which they were applied.

Prayer cylinders designed for automatic repetition of the Buddhist mantra are unlikely to have been produced before the reign of K’ri-srong-Ide-brtsan in AD 755–797 when Buddhism conquered Tibet. It is unlikely that such cylinders were turned by the wind at this period, although no doubt there were prayer flags fluttering in the wind from around this time. Early in the twelfth century, a new fashion for mechanical piety swept China, but again it seems doubtful whether this included wind-powered prayer wheels, which must therefore be placed later, and certainly therefore after the Persian mills.

More is known about the adoption of the windmill in China. Once again early dates for this have been suggested, but these are doubtful. In about AD 1230, Yelu Chu Zai was captured by Jinghi Khan and became his minister. He was an extremely good scholar, administrator and mathematician. An accurate description of the Persian windmill has been discovered in his memoirs, with a comment on how good it would be if the Chinese used it. A Chinese book of the seventeenth century, the *Zhu Qi Tu Shu*, describes the windmill as if it were a European invention, which could be a mistake for Persia. In China, these mills were used for raising water and evolved into an entirely different form from the ones in Persia or Tibet.

Chinese horizontal windmills are still used today along the eastern sea coast north of the Yangtze and in the region of Thangku and Taku near Tientsin to operate chain pumps through gearing for raising salt water for salt pans or fresh water for irrigation. Once again they have no elaborate structures for directing the wind onto the rotors but are closely linked to the way the sails of junks operate. Canvas-covered sails are mounted at the ends of radial arms, each with its own mast, in such a way that they can be spread to catch the wind on the side of the rotor turning away from the wind and be feathered to present the least resistance on the side turning against the wind. The sails can pivot on these masts, and, as on a junk, the sail extends to the front of the mast. The longer, or driving, side of the sail is tied to the rotor framework by a piece of rope of such a length that, when the sail is turning with the

wind, it is held into the wind, but can rotate out of the wind when advancing against the wind. The angle of the sail can be set by the length of rope to a position in which the wind can do useful work on it for more than 180°.

These mills must have been the most efficient of the horizontal types developed before the twentieth century, but all horizontal windmills suffer from the same problem, that only a small part of the wind rotor can be used to its maximum efficiency at any time. The theoretical maximum power coefficient for a simple horizontal windmill is only one third, but in practice it will be much less. These are the reasons why the horizontal windmill has not been developed further and few examples remain at work today.

In the eastern Mediterranean, at some period during the Middle Ages, vertical windmills appeared with a different type of sails from those normally used in the West. The horizontal wind shaft was extended in front of the mill like a ship's bowsprit so that ropes from it could help to stay six or eight radiating spars. The sails were triangular pieces of canvas like the sails of a modern yacht and worked in the same way. The leading edge of each sail was attached to the spar, round which it could be wrapped to reef it in strong winds. The free corner was secured by a rope in much the same way as a ship's boom. These sails were much lighter than those of a conventional western windmill and have found a new application in water pumping mills in some developing countries today.

Wine in Anatolia

Alexia Smith

The quest for the earliest evidence of viniculture has led many scholars to Transcaucasia and Anatolia, the latter of which spans the Asian portion of modern-day Turkey and derives its name from the Greek for "Land of the Rising Sun". It is not known precisely when viniculture (the cultivation of grapes for wine) or viticulture (cultivation of the vine) as were first practiced, but both were well established in Southwest Asia by the beginning of the third millennium BCE. Several lines of evidence have provided insight into early wine production, including textual accounts, archaeological data such as drinking vessels, chemical analyses of residues within vessels, and ancient plant (archaeobotanical) data, as well as modern biogeographical observations.

The modern distribution of wild grapes is useful for demarcating the area within which grape domestication could have occurred in the past. Today, wild grape (*Vitis vinifera* L. subsp. *sylvestris* [C.C. Gmelin] Berger), is found as a forest climber along the coastal regions of central and southern Europe, areas surrounding the Black Sea, and the southern reaches of the Caspian Sea, with isolated patches growing in Turkmenistan and Tadjikistan. Anatolia clearly falls within this natural range.

Archaeobotanical remains provide more detailed information. (See ► [Agriculture: Ancient Methods](#) of Agriculture by Alexia Smith in this volume for a more detailed description of archaeobotanical remains and their recovery.) In general, wild berries are smaller and more acidic than their domesticated counterparts. While entire grape berries can be found, archaeobotanists most typically encounter charred pips which tend to become shorter and rounder following domestication. In practice, however, distinguishing between wild and domesticated grape pips is challenging, since

considerable overlap in their shape and size exists. Consequently, determining the precise point in time when grapes became domesticated is difficult. What is clear from the archaeobotanical record is that wild grapes have been collected for millennia to be eaten fresh or dried. Fermentation of grapes into wine requires fruit with a minimum sugar content of 10 % and the presence of the principal wine yeast, *Saccharomyces cerevisiae*, which naturally occurs on grape skins. Experiments with wine making may have taken place as early as the Neolithic period (ca. 10,500–5500 BCE), well before viticulture developed as a specialized venture. Some of the earliest grape finds come from Öküzini Cave in southwest Anatolia, and date to the Late Palaeolithic (16,000–10,500 BCE). Grapes also appear consistently during the Neolithic and Chalcolithic (5500–3000 BCE) periods at sites such as Can Hasan III, Çayönü, and Korucutepe. From the Chalcolithic to the Early Bronze Age (ca. 3000–2000 BCE), a rapid increase in the presence of grapes at sites such as Kurban Höyük in southern Anatolia reflects the growth of viniculture.

Changes in the range of Early Bronze Age pottery vessels are also linked with an intensification or expansion of viniculture. At this time chalices and other forms associated with drinking such as the *depas amphikypellon* (a tall, narrow, two-handled tankard) began to increase in number. Other drinking vessels associated with wine include *rhyta* (sing. *rhyton*), which were fashioned out of metal or ceramics in the form of an animal's head. Storage vessels include amphorae (An amphora is a jar, usually made of clay, with a narrow neck and two handles, used by ancient Greeks and Romans for holding oil or wine) and large pithoi (Pithoi were large ceramic storage jars, mainly used for storing agricultural produce such as olive oil, wine, olives, raisins or grain. Such large jars must have been made in several sections and joined together before firing). At sites such as Boğazköy and Alişar Höyük, containers fashioned after a cluster of grapes have been found. The association of vessels with wine

can be affirmed using infrared spectroscopy through the detection of tartaric acid, a compound that occurs naturally in grapes and forms the primary acid within wine. Tartaric acid was detected in a large ceramic tub found in Early Bronze Age levels at Titriş Höyük in southeastern Anatolia, linking it with activities such as grape pressing.

Early texts written in Assyrian dating to the Old Assyrian Colony Age (ca. 2000–1750 BCE, corresponding with the Middle Bronze Age) and the Hittite period (ca. 1600–1200 BCE, Late Bronze Age) have been synthesized by Ronald Gorny and provide additional insights into early wine production. Texts from Cappadocian trading colonies refer to the months of September and October as *qitip karānim*, the “harvesting of grapes” season. Grape harvesting festivals are also mentioned in Hittite texts (EZEN ^{GIŠ}GEŠTIN *túh-šu-u-wa-aš*). In Hittite, grapes or grapevines were called *wiyana* (which features in the etymology of the word “wine”) and are represented in texts with the Sumerogram ^{GIŠ}GEŠTIN. The official position of “GAL.GEŠTIN” is mentioned in the *Palace Chronicle*, an Old Hittite text that documents the court during the reigns of Hattušili I and Muršili I. The early responsibilities of GAL.GEŠTIN included supervision of vineyards and their products, which underscores the importance of vineyards as an elite enterprise. Since the majority of the texts document political, economic, and religious matters, bias in the records exists, and little is known about grape production or wine consumption among the general populace. It seems fair to link early viniculture with the elite, however. Since grape vines require a number of years to become established and yield fruits, only people of means could make such a commitment outside of a garden setting. Alexander Joffe even argues that production of alcoholic beverages may be linked to the rise of the state by allowing emerging elites to increase their level of power through surplus production and control over craft production.

A number of Hittite laws pertaining to viniculture bear testimony to well established

practices and likely reflect concerns of earlier time periods. The laws clearly outline relative worth of various commodities and assign appropriate penalties for theft or damages to property. Damage to a vineyard is covered by Law 113, whereby the guilty party must take the damaged grapes and provide grapes from their own vines. Penalties for theft are discussed in Law 101 and combine monetary compensation with corporal punishment involving a spear. Over time corporal punishment was stricken from the law and the fine increased from one shekel per vine to six shekels for a free individual and three shekels for a slave. One Hittite shekel is roughly equivalent to 12.5 g of silver and could purchase 2 *parīsu* of wine, 3 *parīsu* of emmer wheat, 6 *parīsu* of barley, or 160 shekels of copper. Each *parīsu* is believed to correspond with 30 l.

While wine was undoubtedly valued as a pleasing beverage, its earliest uses were restricted to Hittite rituals, festivals, and religious ceremonies, which in general were conducted to gain favor of the gods with respect to the particular issue or problem at hand. Offerings of wine to the gods are mentioned in several Hittite prayers, including the *Prayer to Tešub of Kummani*, the *Prayer to the Sungoddess of the Underworld*, and the *Prayer of Muwatalli to the Stormgod Piḫšašši*. A number of myths, such as the *Ašertu Myth* and the *Myth of the Serpent Illuyanka*, discuss the inebriating power of wine and the potential dangers of becoming intoxicated. The cleansing nature of wine is stressed in several medical rituals, and similarly in rituals intended to purify land and prepare ground for the founding of a new palace. Soldiers also used wine as a metaphor for blood during an oath pledging ritual intended to secure their loyalty.

The association of wine with ritual and religious beliefs perpetuated for some time. During the Lydian period (687–546 BCE) in western Anatolia, Bacchus was celebrated as the god of wine. During Byzantine times in the early part of the first millennium A.D., wine was believed to be blessed by the sky-god; vineyards and stored wine afforded protection from evil spirits. Wine production decreased significantly following the

conversion of Anatolia to Islam, although wine has continually been drunk. Today wine production is increasing again and grapes are widely cultivated in many parts of Turkey, including the Mediterranean coast and Central Anatolia.

Winemaking and Viticulture in the Ancient Near East and Egypt

Virginia R. Badler
Philadelphia, PA, USA

In the ancient Near East and Egypt the development of winemaking and viticulture has a discontinuous record due to the nature of both historical and archaeological evidence. Historical records include texts and pictorial evidence illustrating grapes, grape vines, wine production, and wine consumption. Tracing winemaking and viticulture to its more distant origins in prehistory is now possible through careful archaeological investigations and scientific and chemical analyses. A significant step toward understanding how scant prehistoric evidence could contribute to reconstructing the presence and manufacture of such a specific, delicate and liquid substance as wine emerged with the observation of stains on the interiors of certain pottery jars and the subsequent chemical analysis and identification of key components of these residues. Badler, McGovern, and Michel (1990) pioneered chemical residue analysis (the identification of tartaric acid as a marker for grapes and wine) coupled with archaeological evidence to establish new data points in ancient winemaking history. Guasch-Jané et al. (2004) have further differentiated red from white wine by the presence of malvindicin-glucoside and its unique by-product, syringic acid.

Prehistoric Wine and Ancient Viticulture

Because of extensive cultivation, crossbreeding, seed dispersion, and deliberate transplantation, it is difficult to determine by grape genetics alone the geographic origins of winemaking and viticulture. Probably they are located in the general area of the wild Eurasian grapevine (*Vitis vinifera sylvestris*) that presently grows from Spain to Lebanon, inland along the Danube and Rhine Rivers, around the Black Sea and southern Caspian Sea, at the headwaters of the Tigris and Euphrates Rivers, and farther east in Central Asia (McGovern, 2003, p. 7). Winemaking preceded viticulture, as grape cultivation is not necessary to make wine – it can be made from the wild grapes that were plentiful in certain areas of the Near East. The development of winemaking could have followed a similar path as that of breadmaking and the cultivation of grains. The motivation for both grape and grain cultivation would have been to provide convenient local sources and a stable supply of raw materials for the end products. Viticulture, the purposeful cultivation of grape vines, would have also provided the opportunity to exercise more control over both grape quality and quantity. If there were no wild grapes in the area, a taste for wine imported from other regions would motivate the transplantation of grape vines to secure a local supply of the beverage.

If burnt or carbonized, grape pips (seeds) can be preserved for many centuries. However, it is difficult to determine whether these ancient grape pips are from wild or cultivated grapes, due to variations in the pips themselves and the shape changes that occur when they are carbonized. Carbonized grape pips have been found in many areas of the Near East and Egypt, dating to 3000 BCE or earlier: Susa and Hajji Firuz Tepe in Iran; Hama, Mureybit, Abu Hureyra, Aswad, Jawa, Tell esh-Shuna, Ohalo, Jericho, “En Besor and Bab edh-Dhra” in the Syro-Palestinian area; and Buto, Minshat Abu Omar, Tell Ibrahim Awad and Abydos in Egypt (McGovern, 2003, p. 2, Map 2). Many of these areas (Egypt, most of the Syro-Palestinian region, and southern Iran) are now too arid to support the wild grape.

Neolithic Wine ca. 5400–5000 BCE: Hajji Firuz Tepe, Iran (http://www.museum.upenn.edu/new/exhibits/online_exhibits/wine/wineneolithic.html)

Viticulture was likely first established in the Neolithic period (from about 8000 to 4000 BCE), when for the first time in human prehistory there were numerous sedentary villages established in the Near East and Egypt supported by domesticated plants (such as grains) and animals (such as sheep and goats). Fired ceramic vessels first made their appearance ca. 6000 BCE, and it is within these vessels that we can find chemical evidence for the earliest wine.

Hajji Firuz Tepe is located southwest of Lake Urmia in northern Iran, in the Zagros Mountains at an elevation of over 1,200 m above sea level, along the eastern periphery of the wild grapevine's modern distribution. Jars with yellowish and reddish interior residues have been analyzed, and both residues are that of resinated wine. The resin was from the terebinth tree (*Pistacia atlantica*) that grows throughout the Middle East and would have been added as a preservative (McGovern et al., 1996).

Late Chalcolithic Wine ca. 3500–2900 BCE: Godin Tepe, Iran

The chemical analysis of residues in jars from Godin Tepe established that the technique could be used to determine the existence of wine in prehistoric contexts (Badler, 1995; Badler et al., 1990). Wine was found in a distinctive jar type (piriform, with rope decoration in an inverted U shape on opposite sides of the vessel) from two different contexts dating from 3500 to 3100 BCE and 3100 to 2900 BCE. The complete vessel from the later period has a bung hole a short distance from the base drilled after firing, presumably to decant the beverage.

The homeland of viticulture may be Transcaucasia (the region of modern Georgia, Armenia, and Azerbaijan located between the Black Sea and the Caspian Sea). An early sixth-millennium BCE Shulaveris-Gora jar was shown to have

contained resinated wine, making it the earliest known wine jar (McGovern, 2003, p. 75). At Godin Tepe there is an intriguing link between winemaking and the appearance of the first Transcaucasian type pottery. The earliest sherd with wine residue dates from 3500 to 3100 BCE, when there are significant numbers of Late Uruk type artifacts suggesting contact with sites in southern Iraq (such as Nippur and Warka/Uruk) and Iran (Susa). However, the earliest evidence for wine production (a funnel, heavy lid and empty wine jars, as well as a bin perhaps used for treading grapes) date from 3100 to 2900 BCE, when there is a marked increase in the number of Transcaucasian type sherds. In fact, the funnel itself is similar to the Transcaucasian sherds in its method of manufacture (handmade and fired in a reduction atmosphere), and the heavy lid is a Transcaucasian pottery type.

Late Uruk Wine ca. 3500–3100 BCE: Susa, Iran and Warka/Uruk and Tello/Girsu, Iraq

The residues of ancient resinated wine have been detected in Late Uruk type jars (a droop spouted jar, a piriform jar, and a stone vessel with vertical rope decoration) from Susa in southern Iran (McGovern et al., 1997), a droop spouted jar from Warka/Uruk (Badler, McGovern, & Glusker, 1996), and a droop spouted jar from Tello/Girsu in southern Iraq (McGovern et al., 1997). Since grapes will not grow in the hot dry climate of southern Iraq (there are no grape remains from this area), the wine was most likely an import from further north, and perhaps an important commodity in the Late Uruk trade network (Algaze, 1995).

The Early History of Wine in Syro-Palestine and Egypt

Whereas the Near East looked north to Transcaucasia for the introduction of wine and winemaking, archaeological and clay pottery jar composition evidence clearly suggests that the

origins of Egyptian wine and winemaking were to its east from the Levant: modern Israel, Palestine, and Jordan (McGovern, 2003, pp. 85–103). Hundreds of jars containing chemically attested wine and wine yeasts were found in tomb U-j of the first Scorpion king (Dynasty 0) dated by radiocarbon determination to ca. 3150 BCE. The closest stylistic parallels to these jars are from Early Bronze I sites in the Levant, later confirmed by additional scientific analyses. Although the wild grapevine does not grow there today, it flourished in the region in ancient times, beginning in the Epi-Paleolithic period nearly 20,000 years ago (McGovern, p. 212). By at least 3500 BCE, the domesticated grapevine (*Vitis vinifera vinifera*) had taken hold in the region. Very little archaeological or chemical evidence for winemaking has been found so far, although small spouted Iron Age vats could have been used to tread the grapes.

Although there was a royal winemaking industry in the Nile Delta region from as early as Dynasty 3 (ca. 2700 BCE), the wild grape never grew in ancient Egypt. It seems most likely that both the grape vines and the technology for making wine were imported from the Levant. The earliest “wine labels” in the world belong to Dynasties 1 and 2 of the Early Dynastic period (ca. 3100–2700 BCE), and show an already well developed viticulture tradition (McGovern, 2003, 85ff.).

Once local viticulture and winemaking were established in the Nile Delta, it became a source for royal wine. When there were disruptions, however, such as the Hyksos invasion (ca. 1670–1550 BCE), wine was again imported in large quantities from the Levant and, in particular, Southern Palestine. Exceptionally large quantities of wine were imported into the Hyksos capital of Tell el-Dab’a/Avaris located in the east Delta region of Egypt. The Egyptian winemaking industry rebounded (as evidenced by increasing quantities of native Egyptian wine jars) beginning in the earliest Middle Bronze IIA phases (ca. 1950 BCE) at Avaris. There is evidence that the Egyptian Delta supplied the New Kingdom towns and cities at that time. Avaris also has the only excavated winemaking installation in Egypt,

predating Hellenistic times (McGovern, 2003, p. 119). Detailed tomb paintings provide additional evidence for the Egyptian wine industry, from picking and crushing the grapes to filling the jars (the tomb of Nakht at Thebes [1550–1295 BCE]), the addition of additives and stoppering (the tomb of Khaemweset, son of Ramesses II [1279–1213 BCE], at Thebes), and a sequence of grape picking, crushing, pressing, and wine storage (tomb of Intef, Royal Herald under Thutmosis III [1479–1425 BCE], also at Thebes). Chemical analysis of the residues in the wine jars from the tomb of Tutankhamun (d.1327 BCE) established that this wine was made from red grapes (Guasch-Jané et al., 2004).

Wine in the Ancient Near East

There are chemically identified ancient resinated wine residues in a small jar from Warka/Uruk dating to the late Jemdet Nasr/early Early Dynastic period (beginning of the third millennium BCE; McGovern et al., 1997). In the early third millennium BCE, there are grape pips and even grapevine wood identified from the site of Tepe Malyan (ancient Anshan) in the Shiraz region of the southern Zagros mountains (McGovern, 2003, p. 165). Elamite seals depict drinking scenes (most likely of wine) under grape arbors (McGovern, pp. 165–166). Texts from the city of Ur mention a jar full of *geštin* (the Sumerian word for wine). At Tello/Girsu, *geštin* was stored in rooms, and *geštin* was imported from the eastern (presumably the southern Zagros) mountains. Texts mention grapevines growing within walled gardens in and around the region of the city of Tello/Girsu by the end of the third millennium BCE (McGovern, p. 150). The law code of the Babylonian king Hammurapi, dating to ca. 1790 BCE, mentions wine shops. There are detailed accounts of the wine trade (with cities further north) in the archives of the Syrian city of Mari, located along the Middle Euphrates, and dated to ca. 1750 BCE when the city was destroyed by King Hammurapi, and in the archives of the eighteenth century BCE site of Tell al-Rimah/Karana’a in upper Mesopotamia (McGovern, pp. 169–173).

In the first millennium BCE, the Assyrian rulers not only consumed large quantities of wine, but also undertook an ambitious program of planting new vineyards in their territories. The “Assyrian Domsday Book” recorded tens of thousands of vines planted in the upper Balikh River to the east of Carchemish, in the eastern part of their territory at Yaluna, probably north-east of Nineveh, and in the land of Zamua in the district of Sulaymanyah. The Assyrians produced wine described as sweet, good, aged, or strong, and in both red and white varieties. Additionally, some wines were spiked with other ingredients (McGovern, 2003, pp. 190–191). The Nimrud wine lists contain detailed accounts of the distribution of wine rations. In a wall relief of the palace at Nineveh, Assurbanipal and his wife are shown beneath a grapevine bower drinking what is probably wine, similar to the Elamite scene mentioned above. Chemical analysis of residues from a bronze drinking cup from Nineveh, a bronze goblet and pottery “beer jug” with built-in strainer spout, from Uruk (all from seventh to sixth century BCE tombs) tested positive for resinated wine (McGovern, p. 201).

Woodcarving in Malay Architecture

Ismail Said

Faculty of Built Environment, Universiti
Teknologi Malaysia, Sekudai, Johor, Malaysia

Meaning and Significance

Malay vernacular architecture is characterized by timber as the main building material, pitched roofs and woodcarving on some of the building components. As early as the fourteenth century, woodcarving was a significant craft in the vernacular architecture practiced by Malay craftsmen in Peninsular Malaysia and Southern Thailand (Ismail & Ahmad, 2001). Palaces, houses, mosques, gateways, tombs, and *wakafs* (pavilions) are adorned with more than 20 types of carved components (Ismail, 2002). The craft is

an abstract manifestation of craftsmen's ideas into architectural timber components, symbolizing artistic expression into three architectural components: structural, elemental, and decorative (Ismail). The craftsmen or woodcarvers depict five types of motifs, in order of importance: floral, geometric, calligraphy, fauna, and cosmic. These motifs are laid in six geometrical or floral shapes including oblong, square, circle, octagonal flora, semicircle and triangle. In definition, woodcarving is an art of partially removing wood from a board, a block or a plank following specific motifs, patterns, and orders. The art originated from two fronts: the kingdom of Langkasuka from the north, and the Srivijaya empire from the south of the peninsula (Nik Hassan & Nik Abdul Rahman, 1998; Nik Rashidin, 1999). In historical and geographical contexts, Malay timber architecture and carving in peninsular Malaysia stretches from the north in the province of Pattani in Southern Thailand to the south in the state of Johor.

Similar floral, geometric, fauna, and calligraphic motifs appear on nonarchitectural components such as boats, weapons, furniture, grave-markers (Fig. 1), house utensils, and musical instruments. The most elaborate carving on a boat is the *makara* carved in relief and perforated styles depicting mostly flora and sometimes figurine motifs. The hilts of kris (Fig. 2), *badek* (small dagger), and spears are some of the weapons that are intricately carved on timber such as *kemuning* (*Murraya paniculatum*), *leban* (*Vitex pubescens*), *sena* (*Pterocarpus indicus*), or *nibong* (*Oncosperma tigillarium*). The craftsmen also showed their ideas and skills on more than 15 types of furniture and house utensils.

In carving Malay craftsmen demonstrated high skills of art changing abstract ideas into physical beauty. This developed through a long apprenticeship whereby the skills and knowledge of woodcarving were passed on. By imitating a carved masterpiece, a woodcarver gradually modified the motifs and produced his own design onto the timber piece. For example, a motif of leaves and buds of *ketumbit* or *getamguri* (two shrubs) are gradually modified by the carvers to demonstrate their own stylish identity

Woodcarving in Malay Architecture, Fig. 1 A grave marker (Nik Rashiddin, 2003)

called *air-tangan*, but they keep the fundamental motif form (Nik Rashiddin, 1999). This pattern becomes the trademark, both for the craver and for his architecture or craft. Differences in motifs, layouts and perforations occur from one region to another. For example, craftsmen in the northeastern states of Kelantan and Terengganu depicted different floral motifs from the central states of Negeri Sembilan and Melaka. The motifs of woodcarving signify the identity of the carvers in a region. In spite of the differences, Malay craftsmen observed three common aspects: (a) applying four principal design forms, (b) deducing motifs from home landscape elements, particularly flora and fauna, and (c) manifesting natural beauty as a devotional act to the Creator and as a gift to his fellow men (Mohd Taib, 1997).

The degree of complexity in carving varies from one component to another; intricate, or complex ones include door leaves and wall panels, and simple carvings include gable board and fascia board. From the carving characteristics including motifs and types of perforation and incision, one could differentiate the architecture of one state from another. For example, a large

Woodcarving in Malay Architecture, Fig. 2 A kris hilt (Nik Rashiddin, 2003)

gable board distinguishes a Terengganu house, whereas a large-latticed gable portrays a Perak house. As one gets closer to the carved components, the distinction is further distinguished by the composition of the motifs. The elevation of the Terengganu house is adorned with perforated wall and ventilation panels of varying sizes carved in floral motifs: leaves, tendrils, and flowers of local plants such as *ketumbit*, *getamguri*, *keraknasi*, *jari buaya*, and *bakawali* (Ismail, 2000; Ismail & Ahmad, 2001). The panels of Perak houses are carved in different floral motifs including sunflowers and *ketola*, sometimes mixed with cosmic motifs. These are regionally specific motifs found in Malay woodcarvings in Peninsular Malaysia. However, similarities occur in depicting geometrical motifs on veranda railings or tall window and fascia boards. Likewise, similar Arabic calligraphy motifs are depicted on door and window ventilation panels.

Architectural Components

Carved building components can be categorized into three types: structural, elemental and ornamental. The structural components include *pemeleh* (bargeboard), *tunjuk langit* (king post), cross beams, stringers of stairs and braces. The *pemeleh* is the most prominent component in palaces, aristocratic houses and mosques in the state of Terengganu and in Kelantan. These differentiate the vernacular architecture of this region from other states in peninsular Malaysia. For example, a palace known as tele house, built by Sultan Zainal Abidin in 1868 in the city of Kuala Terengganu, Terengganu, has two pairs of *pemelehs*, one at the *rumah ibu* (main building) and the other at the *rumah tengah* (subsidiary building). Likewise, Langgar Mosque in the city of Kota Bharu, Kelantan, also has two pairs of elegant *pemelehs* with a simple motif of barking deer on its three-tiered roof (Marsiti, 1976). This exterior component handsomely extends the profile of the building toward the sky, making the mosque a landmark in the settlement.

The next important structural carved component in a house or a mosque is the *tunjuk langit* (kingpost). It supports the roof by holding the ridge beam and rafters. The Kampong Laut mosque in Kota Bharu has eight carved *tunjuk langits* (Zahar, 1989). This timber mosque is perhaps the oldest timber mosque, perhaps 170 years old, in Peninsular Malaysia (Ismail, 2001). The *tunjuk langit* distributes the roof load to the tie beams. The lower end usually is attached with a carved component called *buah buton*. This is an ornamental piece which covers the tenon and mortise joint of the *tunjuk langit* to the tie beam. In contrast, the Telok Manok mosque in Southern Thailand has three *tunjuk langits*, joining the three-tiered roof to the tie beam one above another (Ahmad, 1998) (see Fig. 3). They are beautifully carved with lotus blossom motifs and their ends are equipped with *buah butons* using similar motifs. The *tunjuk langits* and *buah butons* greatly enhance the beauty of the interior. Apart from the *tunjuk langit* as a structural member distributing the roof load to the tie beams, braces, or brackets are also structural components supporting the tie beam load to the post. In the Kampong Laut mosque, braces are elaborately carved in shallow relief with lotus blossoms as centerpieces framed by leaves of a different plant in an intricate arabesque.

There are at least five carved elemental components in Malay houses and mosques. These are essential components that make up the entrances and fenestrations. They are the ventilation panels of doors or windows, door or window leaves, walls, railings and gates. Ventilation panels characterize the architecture of a region. For example, the Tengku Long palace in Kuala Terengganu has 15 tall windows at its *rumah ibu*, the main house, with perforated ventilation panels (Fig. 4a, b). Each panel was designed with different floral motifs in symmetrical and asymmetrical layouts. They are part of the fenestration of the building, allowing air and light in. These perforated boards are placed on top of doors, windows, or walls allowing circulation of air and light into the building. More elaborate motifs, a combination

Woodcarving in Malay Architecture,

Fig. 3 Elevation of the Telok Manok mosque in Southern Thailand illustrating the carved components (KALAM, Universiti Teknologi Malaysia, 1998)

Woodcarving in Malay Architecture, Fig. 4 (a) A tall window at Tengku Long palace, an example of Terengganu. (b) A ventilation panel with arabesque floral motif on top of a window

of Quranic calligraphy bordered by floral motifs, are carved for interior door ventilation panels as can be seen in Fig. 5a.

Some ventilation panels are carved in simpler forms, as in the Telok Manok mosque (Fig. 6).

A floral motif of a weed called *ketumbit* is abundantly carved on the ventilation panels which are located around the building and are placed above the walls, windows and doors. The carvings transformed tender leaves of *ketumbit* into an

Woodcarving in Malay Architecture, Fig. 5

(a) A ventilation panel on top of an interior door of Tengku Long palace. (b) A panel with Quranic calligraphy and arabesque floral motifs

Woodcarving in Malay Architecture, Fig. 6 Floral motif on ventilation panels at the door and wall of Telok Manok mosque (KALAM, Universiti Teknologi Malaysia, 1997)

arabesque form both in relief and perforated styles. The perforations not only allow air to flow into the building but also permit light to illuminate the interior. This is often dark because the interior is covered by the pyramidal roof and also because of the dark hue of the timber walls and the underside of the roof. The late afternoon sun casts intricate shadows on the praying space when light passes through the carved panels. This phenomenon adds beauty to the interior setting of the mosque. At night, the scene would be reversed when light from lamps passes through the perforations casting a silhouette of the carved panels. The silhouettes of arabesque and geometric forms can be clearly seen from outside

especially in the absence of light from other surrounding buildings. Therefore the perforated panels add to the characterization of the mosque architecture.

Inside a timber mosque, the *mimbar* (pulpit) demands the most appreciation from the congregation. It is a piece of liturgical furniture from which the *iman* delivers his sermon (Zaki, 1978). The *mimbar* of Kampong Laut mosque is profusely decorated with perforated carvings of floral motifs. The most prominent panel is the front carved board attached to the canopy carved in *gunungan*, one of four principal forms. It resembles the form of the headdress worn by Malay women in the marriage ceremony. The side and

Woodcarving in Malay Architecture,

Fig. 8 Image of soms at Masjid Telok Manok (KALAM, Universiti Teknologi Malaysia, 1997)

back walls of the *mimbar* are fully furnished with perforated carved panels as part of the structural component of the four posts.

The gate is also an elemental component for vernacular Malay architecture; it demarcates the access to a palace or an aristocratic house. It is installed as part of the wall or fence in single or double-leaf doors. The leaf is generally carved in simple floral motifs with straight railings, as in the gate of Kota Lama Duyong, an aristocratic house built in 1920 in Kuala Terengganu (Mohd Hanif, 1997). This house has five types of gate incorporated with a concrete wall surrounding the building. Big and double-leaf gates are meant for honored guests located at the front yard of the building compound (Fig. 7a). Smaller single or double-leaf gates are located near to the kitchen

and deck leading to the rear of the house and are used by the residents and neighbors (Fig. 7b).

The third type of carved components found in Malay vernacular houses and mosques are ornaments. *Som* and *buah* buton are ornaments that are carved and attached to the structural members of the building. *Som* is the decorative component located at the ridge end of the pyramidal roof (Fig. 8). Each roof tier has four *soms*. Langgar mosque has the largest and most elaborate *soms* on its first and second roof tiers. A pair of *pemelehs* accentuates the third tier roof. From a considerable distance the *soms* and *pemeleh* accentuate the profile of the mosque, giving it a distinctive vernacular style. Telok Manok mosque has the most *soms*; each ridge end and minaret roof is decorated with floral motif *soms*.

Woodcarving in Malay Architecture,

Fig. 9 Lotus blossom motif on *buah buton* at Masjid Telok Manok (KALAM, Universiti Teknologi Malaysia, 1998)

Another ornament that gives character to the timber mosque is the *buah buton* – a decorative component attached to end of *tunjuk langit* jointing the tie beam or rafter to the tie beam. The attachment hides the tenon and mortise joint and is not a structural part of the building. Telok Manok Mosque has the most *buah buton* – 18 at the tie beams and three at the end of the *tunjuk langits*. All the carvings are in lotus blossom motif, but each differs in form, resembling the natural form of the flower that shrinks in the morning and gradually opens during the day (Fig. 9). The differences in form resulted from the interpretations of several craftsmen.

Types of Motif

Malay craftsmen applied five types of motif: floral, geometric, calligraphic, faunal, and cosmic onto the carved components. Flowers dominated Malay woodcarving; the carvers used the fruit, stems, tendrils, leaves, and of course the flower. Fruit of pomegranates, lotus flowers, sunflowers, *ketumbit*, *ketola* and *bakawali*, leaves of *getamguri*, and stems and tendrils of *ipomea* are depicted in a variety of abstract forms. The pomegranate is chosen as a motif because of its interesting shapes and bright orange flowers. The lotus is selected because of its auspicious

status and sacredness. Furthermore, weeds such as *ketumbit* with bright yellow flowers and *getamguri* with wavy foliage are recognized by Malay craftsmen in Terengganu and Kelantan; they translated their beauty into the tangible art (Fig. 10). Craftsmen in Perak and Negeri Sembilan favored bright yellow flowers and the intertwining character of *ketola* and large, bright sunflowers on their door leaves and ventilation panels. Malay craftsmen observed the beauty of their surroundings and transferred their intangible value into a physical product that could be appreciated by others.

Fauna are rare in Malay woodcarving because Islam prohibits depicting figurine motifs. However, a few craftsmen still carved fauna motifs such as: (a) a pair of fighting cockerels on a window ventilation panel of a Negeri Sembilan house, (b) a group of ducks waddling in a row on a stringer of a Malacca house, and (c) a lizard head on a corner of a fascia board of a Perak house (Abdul Halim, 1986). These motifs are generally carved in abstract forms, hiding the real figure of the fauna.

Calligraphy is also applied as a motif at wall and ventilation panels on Kelantan, Terengganu and Negeri Sembilan houses. It is either carved in relief, perforated or a combination of both. The Malay craftsmen put Quranic verses into wood panels written in several Arabic styles.

Woodcarving in Malay Architecture, Fig. 10

A ventilation panel of Kota Lama Duyong in Kuala Terengganu carved in floral motifs, getamguri and sulur kacang (KALAM, Universiti Teknologi Malaysia, 1997)

Woodcarving in Malay Architecture, Fig. 11

A wall panel carved in traditional calligraphy motif at a house in Kampung Pulau Panjang, Kelantan

An excellent example is a wall panel at a house in Kampung Pulau Panjang, Kelantan where a Quranic verse is carved in perforated form and laid symmetrically on an axis (Fig. 11).

This carving demonstrated the craftsman's devotion to Islam and adoration of the *Quran*. The legacy of calligraphy in Malay letter writing has contributed woodcarving, which has selected it as one of its motifs (Syed Ahmad, 1992).

In addition to arabesque motifs, Malay craftsmen also apply geometric motifs on door leaves, ventilation panels, wall panels, railings, and partitions. The configuration can be a series of diagonals repeatedly copied throughout the component. Swastikas and stars are more complex motifs that dominate the carving configurations, for example, on a ventilation panel of a wall. Repetition of similar motifs creates a sense of beauty and contrast against adjacent foliate or calligraphic motifs. The motif of the swastika, which originated from Chinese woodcarving, can be seen in ventilation panels of Kota Lama Duyong (Mohd Hanif, 1997). Geometrical motifs are easier to carve than the other four types and thus repetitive components such as railings are done by apprentices or sometimes wives of the master craftsmen (Nik Rashiddin, 1999).

The motif of the cosmos is seen the least in Malay woodcarving. The depiction of this motif in Malay carving illustrates the influence of Chinese craftsmanship and the pluralism of

cultural values in vernacular architecture. A ventilation panel at Mohd Ali Kulup Mat Yassin's house in Perak is an example where leaf and flower are combined with a cloud.

Principal Forms and Shapes of Carved Components

In terms of iconography, Malay woodcarving depicts four principal forms including *stupa*, *makara*, lotus and *gunungan* (Fig. 12).

The *stupa* form can be found in house components such as buah buton or on the newel posts of stairs or gates. These are decorative components that enliven the interior of the building. Buah buton is attached to the end of the kingpost hiding the tenon and mortise joint to a tie beam of the roof structure. It is the only volumetric component that becomes the jewel of carving, beautifying the interior of the house. The *gunungan* is a silhouette of a mountain or tree of life, a symbol of status. The gateway of a house compound is carved in *gunungan*, but other components including the ventilation panel of the door or window and door leaf also used this form. The *makara* reflects the center of the cosmological imagination for a mythological sea monster in Pattani and Kelantan. Gable-end boards on Terengganu or Kelantan houses depicted the form of *makara* that enhanced the façade of the

Woodcarving in Malay Architecture,

Fig. 12 Principal forms of Malay woodcarving

Woodcarving in Malay Architecture, Fig. 13 Shapes of carved components in the Malay houses

building. This component differentiates the form of the house in Terengganu and Kelantan over houses in Perak and Negeri Sembilan. The lotus is a symbol of purity, and its form is applied to a variety of house components, including door leaves, fascia boards, ventilation panels and buah buttons. Apart from house components, the form is carved at the foot of tombstones and bases of kris hilts (see Farish & Khoo, 2003).

The carved components are designed in six geometrical or floral shapes including oblongs, squares, circles, octagonal flora, semicircles, and triangles (Fig. 13).

Squares and oblongs are common layouts for many components, particularly door leaves and ventilation and wall panels. They are easier to carve than flowers or circles since their outlines are straight. Ventilation panels on doors, windows, and walls of Terengganu and Kelantan houses are dominated by these perforated components in floral motifs. The layout and size of the components are proportionate with the elevation of the building and volume of its interior space. The house builder and craftsmen carved sufficient amounts of fenestration to allow cross ventilation to give thermal comfort to residents without depending on mechanical means (Ismail & Ahmad, 2001).

Occasionally, a floral octagonal or circle layout is carved for special components such as the base of a ceiling lamp. Such carving can be found in aristocratic houses such as Kota Lama Duyong. The intricacy of the shape and carving

denotes the skillfulness of the Malay craftsman and wealth of the house owner.

Apart from the shapes, the carvings are generally symmetrical on at least one axis. The axis orientates the carving pattern, repeating the pattern from left to right or from the top to the bottom of a component. Figure 14 illustrates a perforated carving of a wall panel of Wan Embong house in Kuala Terengganu. Most ventilation panels, wall panels, door and window leaves, and flat railings are done in symmetrical formats with floral motifs.

Factors Influencing Timber Selection

Generally, Malay craftsmen would apply three factors in selecting appropriate timber for their carvings. The factors include availability of timber, its physical characteristics and durability, and the craftsmen's spiritual beliefs toward the timber species. The hierarchy of selection depends on the type of carved components. For example, the making of house components such as door leaves or ventilation panels is clearly determined by the availability of timber which could easily be obtained in large volume. On the other hand, the Malay craftsmen chose only kemuning or kenaung for making kris hilts and sheaths because of their fine interlocked grains and deep yellow sapwoods overlapping with dark brown heartwood. In addition, these timbers are regarded as possessing good spirit that must be

Woodcarving in Malay Architecture, Fig. 14 A perforated, arabesque wall panel carved in a symmetrical layout with a vertical axis

respected and that will accompany the weapon (Faris & Khoo, 2003; Ismail & Ahmad, 2001).

Availability of Timber

Tropical rain forests of Peninsular Malaysia produce a variety of quality, durable timber grown in the low-lying undulating land and hills of the Main Range (Appanah, 1993). Heavy hardwood species such as *chengal* (*Balanocarpus heimii*), *balau* (*Shorea spp.*), and *merbau* (*Intsia palembanica*) are the favorites. They are durable species that resist attacks from termites, powder-post beetles and fungi, which would harm their structural properties including flexibility, stiffness, and hardness. These are suitable for making large building components such as door leaves, bargeboards, kingposts, wall, and ventilation panels as well as small ones including railings and buah butons. The same timber species are used to make structural building components

such as posts, beams, and floorboards as well as the carved components. It is common to find an entire house made from *chengal*, *balau*, or *merbau* in the states of Terengganu, Kelantan, Perak, and Pahang in the peninsula. For example, a house at Kampong Bolok in Pahang built in the 1920s, was constructed wholly from *merbau*.

The timbers are air-dried under a shed or under the houses, allowing prevailing winds and the sun to dry them while protecting them from the rain. No preservative treatment is applied to the timber since the resins of most dipterocarps are able to resist the powder-post beetles, termites, and fungi attack (Farmers, 1987). The drying (seasoning) process may take months or even years for some timber species particularly *kemuning*, *kenaung*, and *sena*.

Medium hardwoods from the forests such as *medang* (*Litsea grandis*), *kundang hutan* (*Bouea macrophylla*), and *keladan* (*Dryobalanops oblongifolia*) are sometimes used for carving door leaves, furniture such as beds and cabinets, and musical instruments such as the *kenong* and *kompang*. These timbers are more prone to attacks from powder-post beetles and fungi and thus they are placed where they will not come into contact with moisture.

Craftsmen would optimize timber choice by harvesting readily available fruit trees grown in house compounds and orchards. They would cut large branches or sometimes the trunk of mature trees including *ciku* (*Achras zapota*), jackfruit (*Artocarpus heterophyllus*), *rambai* (*Baccaurea bracteata*), *belimbing* (*Averhorra belimbii*), *bacang* (*Mangifera foetida*), and *kundang* (*Bouea macrophylla*). Since these timber pieces are relatively small, the craftsmen would carve them into household tools and utensils and musical instruments in floral and geometrical relief motifs. The tools and utensils include coconut graters, ladles, food containers, biscuit moulds, and *rehal* (a cradle in which to place the *Quran* during readings). The practice of consuming timber from cultivated trees suggests that the Malay craftsmen were attentive to their environment.

Timbers for carving were also extracted from the secondary and coastal forests where mixtures of heavy, medium, and light hardwood species

grow. *Leban* (*Vitex spp.*), a heavy hardwood, and *sena* (*Pterocarpus indicus*), a light hardwood, are the common species obtained from the secondary forest for making sheaths of badek or kris and for carving some utensils. The craftsmen living in coastal villages would harvest timber from *penaga laut* (*Calophyllum inophyllum*) and *kelat jambu laut* (*Syzygium grande*) from the beach forest. They were carved for boat paddles and grave markers. Malay craftsmen optimized the timber found within or adjacent to their environments.

Physical Characteristics and Durability

In woodcarving, the physical characteristics that govern the suitability of timber are durability, color, grain and texture, and luster. Before working on the timber, the craftsmen select a timber piece that is free from all defects, namely, knots, pith flecks, resin streaks, brittlehearts, checks and splits, decay, bowing and cupping (Nik Rashiddin, 1999). Durability of hardwood is directly related to density; high density generally suggests strong resistance against fungi decay and boring insect attacks. Therefore, chengal, balau, resak, and merbau are the preferable species for most house components including structural, elemental, and decorative types (Watson, 1928). Buildings made from these species are known to last for more than 150 years. Their resistance is possibly due to the silica deposits in their storage tissue (Desch, 1981).

In some heavy hardwoods there is no color distinction between sapwood and heartwood, but usually the heartwood is more deeply colored (Desch, 1981). On exposure to the air, chengal and balau are light brown to dark red-brown and become darker as they age. On the contrary, the merbau's sapwood is pale yellow sharply defined from the dark red-brown heartwood. Generally, the final finish of the carved timber components made from these heavy hardwoods is finished with sandpaper. In carving house components, the craftsmen is less critical about the timber color but very selective when carving weapon hilts and sheaths, furniture and musical instruments. Only kemuning and kenaung, with bright yellow sapwoods and dark brown heartwoods,

are chosen for the hilts of kris, badek and *kerambit* (a small knife). These weapons are considered auspicious tools and used only for ceremonial events or special occasions.

Grain and texture are two distinct characteristics of timber. The grain refers to the direction of the fibers, and texture applies to the relative size and the amount of variation in the size of the cells (Desch, 1981; Smith, 1999). The chengal timber is easy to cut and incise because it has straight fibers and it does not give rise to ornamental figuring. It has a fine and even texture and is thus suitable for almost all carvings, from large features such as a boat's figurehead, to a building's wall panels, to small objects such as rehal. The merbau has a more interesting appearance than the chengal or balau since it has interlocked and sometimes wavy grain and a coarse texture with large vessels and coarse rays (Farmers, 1987). But it is more difficult to incise since it is denser and has a higher hardness, thus it is used for large building components such as posts and seldom used for small crafts such as house utensils.

Lustrous woods such as merbau, kemuning, tempinis (*Sloetia sideroxylon*), and kenaung have cell walls that reflect light, particularly on quarter-sawn surfaces (Desch, 1981). The luster is a natural asset that craftsmen exhibit in carved furniture and small crafts such as kris hilts, knife sheaths, walking sticks, and picture frames. The luster, however, does not last long without a finishing coat over the timber surface. Craftsmen apply several layers of shellac or varnish to a kris hilt to retain the lustrous surface of the kemuning.

Spirit of Wood

In addition to the tangible characteristics of the timber, Malay craftsmen also select timber based on its possessing either a beneficial or malignant value (Farish & Khoo, 2003). Kemuning and kenaung are regarded as the most auspicious species because the craftsmen believe that they possess strong spirits that will accompany a weapon such as a kris, badek, kerambit, or spear. A few craftsmen in Kelantan believe that this spirit is compatible with the iron blade. These timbers are reserved for creating hilts and sheaths of

weapons. As work begins, a craftsman cannot be definite on what style of kris hilt that a piece of kemuning or kenaung will finally become. Gradually, during the incision process, the timber reveals its grain, texture, and luster and only then will the craftsmen know the hilt style the timber will become. The motifs on this hilt would be similar to large architectural components such as leaves of getamguri and jaribuaya, flowers of ketumbit and keraknasi; these are shrubs or weeds commonly found in Malay house gardens (Ismail & Ahmad, 2001; Syed Ahmad, 1992).

Woodcarving is a significant craft in Malay vernacular architectural and nonarchitectural elements. It is a manifestation of craftsmen's imagination using floral, geometrical, calligraphic, faunal, and cosmic. It signifies the identity of a regional architecture as well as a pattern of the craftsmen from a region. In intangible perspective, it illustrates the belief of the Malay craftsmen toward architecture, devotion to god and their contribution to society. To understand the significance of the craft, one needs to investigate its physical forms in term of motifs, principal forms and layouts. In addition, it is important to know the characteristics of the timber species from which the carvings are made.

Woodworking in Egypt

Geoffrey P. Killen

More is known about woodworking in Egypt than anywhere else in the ancient world. By the New

Woodworking in Egypt,

Plate 1 Bed frame, first dynasty, Metropolitan Museum of Art, MMA 12.187.52

Kingdom, Egyptian woodworking had reached its zenith with examples of woodworking such as furniture being highly prized and often sent as tribute to the rulers of neighbouring countries.

Many Pre-dynastic burials in the Nile valley have the body placed on wooden poles and covered with matting made of plant fibre, while some burials are found in primitive wooden boxes. By the unification of Upper and Lower Egypt we find bed frames, Plate 1, in common use with many examples being found in first dynasty (3100–2890 BCE) tombs. The quality of these bed frames ranged from conveniently shaped branches that were lashed together to sophisticated examples made from rounded poles that were jointed together and supported on finely carved bovine shaped legs (Petrie, 1913, Pl. VIII–IX).

At the beginning of the Old Kingdom, which opens with the third Dynasty (2686–2613 BCE), we see major advances in building and the associated trade of carpentry. The quality of royal furniture made during this period can be seen in those examples discovered by the American Egyptologist George Reisner, in the fourth Dynasty tomb of Queen Hetepheres (ca. 2600 BCE) at Giza (Reisner, 1955). When he opened the tomb, he found that the wooden elements from which the furniture had been made had rotted away to powder. However, it proved possible to reconstruct much of the Queen's furniture by studying the positions of the gold sheaths, which had encased the furniture, and the inlays that had fallen free and lay on the tomb's floor. Hetepheres' furniture consisted of two armchairs, bed frame, bed canopy, carrying chair and two boxes. What Reisner and his team achieved, from a pile of unrelated fragments of gold and faience

is remarkable for it has given us a small but superb collection of early furniture, which rivals Tutankhamun's, manufactured over a thousand years later.

We see the introduction of the wooden box at the end of the Old Kingdom. They were manufactured with flat, gable, barrel and shrine shaped lids. Some were very large and were designed with a pair of poles that enabled the box to be carried by a team of porters. In one tomb scene 14 men are carrying a box. During the Middle Kingdom we find boxes were customised to hold cosmetics. Many were designed like crates to hold small alabaster jars, which held perfumed oils. Other boxes have been found to contain mirrors, kohl containers, combs and even a pair of slippers! A box made for Sithathoriunet (ca. 1800 BCE) (Winlock, 1934) was decorated with gold fittings and bezels in which were set with polished carnelian stones. Other elaborate boxes held cosmetics or; these were usually inlaid or veneered with sheets of ivory or exotic timbers bought from lands south of Egypt (Plate 2). Scribes even had boxes in which they stored their writing implements and palettes. Their boxes were usually painted to imitate the stringing and veneered panels found on more ornate boxes.

Important directional changes in Middle Kingdom furniture can be seen by studying the large collection of stelae, which are preserved in the Egyptian Museum, Cairo. These Middle Kingdom stelae show that tables were widely used for the display of vases or holding water pots. Many are low with straight legs and have a single stretcher strung below the tabletop. We also see that Egyptian carpenters were constructing splay-legged tables, which had

cavetto cornice mouldings below the edge of the tabletop (Plate 3). Slender vase stands were made from thin strips of timber braced with cross and angled struts. They were fitted with a shaped collar, which held the round base of a single vase. They were covered with a gesso foundation before being painted to imitate carnelian and faience inlay. Those chairs made during the Middle Kingdom had either short backs over which was draped a cover or cushion or they had backs of full height. Such chair backs were curved and made from angled slats of timber. They stood on slender gazelle-shaped legs. Often chairs were painted to simulate animal skin, which were painted with a technique, which resembles cow skin and was used on an arrow quiver case, which is preserved in the Egyptian Museum, Cairo.

By the New Kingdom, the homes of officials and nobles would have been furnished with a wide range of wooden furniture, the most common of which would have been the stools. Egyptians used a large number of different types of stool. The most commonly used were lattice stools that were made from thin struts of timber with angled braces supporting a double cove seat (Plate 4). Round-legged stools appear in some of the more important Theban tombs. The majority of legs from these stools were hand rounded although there is a small corpus of material, which have legs that appear to be turned. During the New Kingdom we see carpenters sitting on three legged stools, which allowed the stool to rest evenly on the workshop floor. The folding stool originated in the Middle Kingdom and was

Woodworking in Egypt,

Plate 4 Lattice Stool,
eighteenth Dynasty, British
Museum, BM EA 2476

made from two interlocking frames with a leather seat. New Kingdom examples are more elaborate having the floor rails and crossing spindles finished with carved goose head terminals, which are inlaid with ivory to imitate the eyes and neck feathers. We also see that lion legged stools and chairs were used in the homes of high-ranking officials.

The wooden furniture manufactured in the royal workshops was not very different in design to that used by the middle classes. However, they were exquisitely embellished with gold sheet, inlaid with coloured stones and faience or veneered with ebony and ivory. They were also adorned with the uraeus [the sacred serpent found on the headdresses of Egyptian rulers and divinities, representing sovereignty] and the symbols of kingship. Other pieces are inlaid with thousands of slivers of coloured wood in either marquetry or parquetry patterns. In the tomb of Yuya and Tuyu (ca. 1400 BCE), the parents of Queen Tiye and the wife of Amenhotep III (1390–1352 BCE), a small armchair made for Princess Sitamun was discovered. The illustrious examples of furniture discovered in the Tomb of Tutankhamun (1336–1327 BCE) show the

outstanding quality of design and construction achieved by eighteenth dynasty carpenters.

Wool in India

Tirthankar Roy

London School of Economics and Political
Science, London, UK

The submontane, the peninsular, and the arid zones of South Asia are home to indigenous breeds of sheep. In the past, this resource sustained two large handicrafts, manufacture of coarse blankets and knotted carpets. These industries survived into the twenty-first century. With the development of knitting technology, apparel and hosiery manufacture expanded in the region. All of these users of local wool, however, had to deal with problems of quality and supply of the material. This entry surveys the modern history of wool production and usage in the region and shows how changing land use and commercialization shaped these livelihoods. This entry focuses on the twentieth century, because systematic descriptions for earlier periods remain scarce.

Wool Production

South Asia has 5–6 % of the world's sheep population and a somewhat smaller percentage of the world production of clean wool. In the first half of the twentieth century, the region contained the fourth largest sheep stock in the world. Historically, the plains of South Asia had only one major apparel use of wool, warm blankets for winter. A comparably large use occurred also in woolen carpets, which was, and still is, an important export article. Relative to the major wool-yielding breeds of the world, the average Indian sheep yielded a small quantity of apparel-grade wool, but it was a sturdy animal and well adapted to coarse feeding, poor nutrition, extreme aridity, and long migration. Whether due to indiscriminate breeding, or environmental reasons, sheep were raised for meat and manure as much as for their wool.

Very few breeds in India produce apparel wool or fine wool suitable for garments. The

exceptions are Kashmir Merino, which is a crossbreed developed more recently, and Nilgiri. Those that do produce fine wool include products of selective breeding. By and large, the north Indian breeds produce coarser and stronger wool suitable for carpets. Carpet wool has longer staple and is coarser than apparel wool. Wool used in floor coverings needs to be long and strong to withstand rougher usage and greater abrasion than is the case with garments. On the other hand, apparels require softer, that is, fine and short-staple, wool.

Observers of the textile crafts at the turn of the century believed that within the unchangeable climatic constraint, much could still be done to improve the quality of the wool, mainly by selective breeding. Selective breeding was not known to have been widely practiced before British colonial rule began in India (c. 1765). A few farms did start under the encouragement of the state, but did not survive. Only in one instance from the 1880s, Sir Mark Cubbon's experimental firm in the hills of Mysore was a modest success reported in breeding new varieties of sheep.

Many groups of people were reportedly engaged in sheep rearing around 1900. Most of them, however, did not do this as their main occupation. Apparently, sheep farming as such was not economical. Some of these groups, for example, combined it with weaving coarse blankets for local markets and others with trade in wool. Almost all of them were mobile and travelled long distances between seasons in search of good pasture, in keeping with the tropical monsoon climate with its long dry season.

A prominent example was the Bhotias of Kumaon. In the early twentieth century, they were mainly a trading community with partial involvement in sheep rearing and weaving (Hoon, 1996). Groups of them started out on their long treks which combined grazing, spinning, and trade, in mid-Spring, with merchandise financed by a group of bankers called Kharagwals. They traversed two routes connecting the railheads of the plains with the trans-Himalayan passes. The eastern route started from Tanakpur and climbed up along Champawat, Lohaghat, Pithoragarh, and Askot.

The central route began from Ramnagar, went to Haldwani, and ascended via Ranikhet, Almora, Bageshwar, and Johar. Towards the upper reaches, the passes could be so narrow that no animal larger than sheep could negotiate them, so sheep were the natural choice as pack animals. Like the plains shepherds, they spun while the flocks travelled along with them and wove part of the wool, but unlike them, the Bhotias specialized mainly in wool trade. They travelled up to Gartok, Taklakot, and Gyanema markets in Tibet; bought wool along with salt, borax, musk furs, yak's tail, and live animals; and sold in exchange of grain, Spring crops, metal utensils, tobacco, and silver. At the onset of winter began the descent, stopping over at the major fairs of the foothills at Jouljibi, Bageshwar, and Thal where many of the transactions were completed.

From the end of the nineteenth century, formal or informal closures of the commons and wastes reduced the supply of homegrown wool and tended to sever the link between animal husbandry and the production of apparel and blankets. Long-distance trade in both wool and wool products expanded. Sheep rearing relocated towards areas that could support easier grazing conditions. The railways played a role in deciding which regions would specialize in which activity. Thus, the vast arid frontier in Rajputana specialized in wool production; Punjab, with easy access to Himalayan trading routes, carpet production; and the Rajputana grazing lands, emerging as a major market. United Provinces located in the middle Gangetic plains became the major center of the use of wool (Roy, 2003).

The declining access to common resources like pasture was connected with the "peasantization" of those communities who earlier depended on the commons. Chief among these were the sheep herders. Codification of property rights led to many customary rights on open wastes being overlooked. Large canal irrigation systems broke up grazing grounds and converted some of them into cultivable land. Population growth also led to encroachment on forests and grazing grounds. Furthermore, the British redefined their political relationship with pastoralist communities and often imposed new

taxes on them. In most parts of eastern and southern India, adverse economic conditions degenerated the existing sheep stock. Elsewhere, shepherds tended to move into the cities, into farming, permanently migrate in search of pastures, and resettle in zones where no more than tiny flocks could be maintained. They would leave their traditional mixed occupations and specialize in rearing, textile production, or trade. Sheep rearing tended to move towards two regions, western India and southern India. The regions losing sheep were the Gangetic plains. The former regions had one strong common feature: both included extremely arid regions with a plentiful supply of common and grazing lands, although a great deal of it was of poor quality.

In the process, markets and trades expanded in wool, and wool production and wool usage tended to separate. Large flocks disappeared in the Gangetic plains; there was also a fall in the number of shepherds. Yet, the Gangetic plains remained a main source of wool. It got its wool from western India (Rajputana) and from across the northern frontier. In south India, the main rearing region came to be Mysore; its clients were both a local woolen apparel industry and a carpet industry located in Arcot on the south-eastern coast.

Around 1930, the production of wool was estimated at 100 million lbs, import by sea 6 million lbs, and export 45 million lbs. Import by the land frontier was said to be, somewhat unreliably, 20 million lbs. Even with a large reexport, this should put domestic usage of wool at about 70–80 million lbs; the scale of foreign trade was growing steadily in the interwar period. Barring the First World War, the growing import trade consisted of both raw wool and woolen textiles. After the imposition of a tariff on wool manufactures in the 1930s, more raw wool was traded domestically.

The preeminent entrepôt was the Punjab. Here, trans-Himalayan, local, and Rajputana wool was imported, to be reexported towards Bombay, Karachi, and eastward via two or three important market towns. It was this overwhelming involvement in the raw material trade that

subsequently made these towns advantageous locations for power loom and hosiery industries. The most important market for wool in Punjab was Fazilka. But several other towns, notably, Amritsar, Ludhiana, and Multan, also contained important markets. Rajputana's trade was associated closely with Bikaner.

In the late nineteenth century, major Punjab markets such as Amritsar and Ludhiana grew as trading and manufacturing centers. The railways connected the wool markets of Rajputana with the carpet and apparel industries in Punjab. The railway connection along the Gangetic plains also fostered carpet industries in Agra and Mirzapur in the eastern end of the United Provinces.

Except for an end to the trans-Himalayan overland trade, which affected the enterprise of the Bhotias adversely, there was no significant change to these supply conditions in the decades after British colonial rule ended in 1947. Studies on wool production in the late twentieth century revealed further professionalization of the industry, partial success of cross-breeding programs, but also increasingly unstable production conditions mainly owing to variations in the quality of pasture. After 1990, there was a considerable increase in the domestic demand for wool from the carpet industry, which had experienced an export boom. Wool production, however, responded fitfully. In fact, the population of sheep expanded marginally in the arid areas, while declining elsewhere. The fundamental ecological constraints on the industry have progressively become more serious, because of population pressure on common grazing lands (Ray, 1999).

The Textile Industry

The five main uses of wool in India were blankets, carpets, shawls, felts, and garments. In the early twentieth century, the manufacture of woollen garments, so far confined to the cottage industry of handlooms, began in large-scale factories and knitted goods factories. The increasing production of good quality woollen garments was an effect of new middle-class choices as well as

a new raw material, imported worsteds. Felts were a disappearing industry during this period. Shawls were manufactured mainly in Kashmir and remained at a distance from other branches of the woollen textile industry.

Until 1900, a considerable quantity of cotton cloth, usually woven with handspun cotton, was used as winter wear. This use was steadily replaced by woollen garments. Better storage of wools and the growth of a middle-class urban market for garments contributed to this trend. This trend in the market touched wool weaving on handlooms marginally. In 1920, there were 100,000 handlooms engaged in wools in British India and the princely states. For a comparison, cotton and silk handlooms numbered approximately two million. By contrast with cotton or silk, handloom weaving in wool was a minor tradition. The weavers adopted a rough process that dispensed with much of finishing and dyeing. Interestingly, as in cotton or silk, artisanal weaving of wool withstood competition from factories quite well. In fact, the two traditions converged in the beginning when the factories wove wool with hand-powered looms.

The first large-scale enterprises were established in 1876 by the British India Corporation, a north Indian managing agency firm at Dhariwal in Punjab and at Kanpur. Kanpur was an emerging textile mill center, an important army base, and a center of army procurement activity. Both towns were conveniently close to trade routes in country wool. The mills in Bombay and Bangalore that followed in the next decade, likewise, had easy access to traded wool from southern Rajputana and Mysore. Initially, the main business of the mills was to supply mass produced but still handwoven blankets and garments for the army and to spin yarn for the carpet industry. In the 10 years after the First World War, dramatic changes took place. The war forced a rapid expansion in weaving capacity in the mills. Considerable excess demand still remained, met by the resources of the cottage handlooms. Many small shops manufacturing tweeds and rugs mushroomed in northern India in response. There was also diversification in product lines. The mills began to make finer

cloth using worsted yarn, for which the wool had to be imported.

The urban handlooms, especially in Muzaffarnagar and Bijnor in the middle Gangetic plains and Panipat and Ludhiana in Punjab, received great encouragement during the First World War, when the Munitions Board began to contract orders in these cities for blankets and smaller articles. Many cotton weavers in these cities shifted to wool, and the existing woolen manufactures expanded and diversified. The war orders were many times larger than the scale of the business before 1914 and were estimated to have used up practically the entire supply of blanket wool in India around 1917–1918.

At the same time, imported better-quality woolen garments altered tastes and introduced new standards. Consumers increasingly did not want the coarse rural blankets. They preferred the finer products made in new weaving establishments in the cities using traded wool. Competition from urban weaving and depletion of pastures adversely affected the practice of weaving by sheep herders themselves.

In this fashion, the more commercialized part of woolen textile industry came to concentrate in a few wool trading towns of northern India. These towns, principally Ludhiana, expanded in woolen knitwear manufacture after independence, thanks to the local manufacture of cheap machines and consolidation of the wool trade. The industry benefited greatly from trade reforms introduced in the 1990s. Easier access to technology, markets, and imported wool acted as a major boost. As small-scale production grew, the large factories stagnated. The British India Corporation had gone bankrupt in the 1970s and was taken over by the Government of India in 1981. It still possesses some of the best-known brands of wool in the Indian market, but the textile industry has developed stronger ties with the world wool market.

Conclusion

The modern history of wool production is a story of increasing concentration of commercial sheep herding from the peninsular and the plains

towards the arid western zone. The shift occurred because of two main factors, changing land use patterns in the plains and the peninsular and the growth of a railway network. The textile uses of wool concentrated too. The range of use narrowed to two main fields, carpets and winter wear, including woven and knitwear, and industrial agglomerations emerged in the wool trading towns of northern India. For four decades after 1947, the industry remained subdued if not moribund. More recently, however, trade liberalization imparted a powerful stimulating influence.

Worked Glass Artefacts in Australia and the Pacific

James L. Flexner
Australian National University, Canberra,
Australia

Volcanic glass, of which obsidian is the most well-known variety, was an important raw material for toolmaking among many different societies (Shackley, 2005). Volcanic glass was often traded across networks stretching over hundreds or even thousands of kilometers because of its great utility as a raw material for cutting and scraping tools. In Australia and the Pacific Islands, indigenous people developed sophisticated lithic technologies (as archaeologists call stone tools), and volcanic glass was an important component of these toolkits (Barrera & Kirch, 1973; Reepmeyer et al., 2011).

In the Old World, a different kind of glass produced by melting quartz minerals (usually sand) developed in the Mediterranean area, notably Egypt, from at least 1500 BCE (Lilyquist, 1993). When Europeans began exploring the Pacific from the end of the sixteenth century CE onward, they brought some of the earliest mass-produced glass objects with them in the form of trade beads and bottles that held alcoholic beverages, medicines, and perfumes, among other commodities. In addition to having an interest in European glass for its exotic origins and beauty, indigenous Pacific Islanders and Aboriginal Australians immediately recognized the value of glass, especially bottle glass, as a raw material for toolmaking. Adapting introduced raw materials like bottle glass to indigenous lithic technologies was not unique to the Pacific region. Worked glass tools have also been recognized throughout the Americas in various colonial contexts, primarily associated with Native Americans (Lindauer, 1997; Shackley, 2000; Silliman, 1997, pp. 160–161) but also on plantation sites in areas inhabited by African Americans (Wilkie, 1996).

Worked glass technologies are identified by archaeologists in the exploration of colonial sites (“worked glass” below will refer to European glass rather than volcanic glass). The identification of this type of artifact is somewhat difficult, because there are many natural processes (e.g., trampling by animals) that can mimic the kinds of conchoidal fracturing (the way that brittle materials break when they do not follow any natural planes of separation) associated with worked glass. Archaeologists have come up with various ways to deal with this problem, including looking for artifacts in areas where these kinds of natural processes are unlikely to occur, looking for high concentrations of flaked glass in activity areas, looking for worked stone and glass tools in the same assemblage, and looking for glass artifacts indicating fracturing or flaking on thicker parts of the bottle, especially around the base (Cooper & Bowdler, 1998; Gibbs & Harrison, 2008). This could be called a “contextual” approach, which uses related information from the context of the finds

to determine the likelihood that fracturing on glass artifacts relates to human activity in the past.

Ethnohistoric information, such as oral histories and the accounts of explorers, missionaries, and other early colonists, can also be useful for interpreting archaeological glass assemblages that appear to show evidence for toolmaking activities. These kinds of accounts might provide an independent line of evidence for the indigenous use of introduced glass as a raw material for tools. Some archaeologists suggest that for certain forms (notably side and edge scrapers), the only way to be completely certain that worked glass artifacts reflect past human activity is to use microscopy to identify use-wear on the artifacts (Conte & Romero, 2008). In practice, both kinds of approaches, microscopic and contextual, can be useful in the identification of worked glass.

For Australia and the Pacific Islands, worked glass technologies are useful artifacts for understanding indigenous technological change, innovation, and identity in an era of colonialism. The best-known worked glass artifact type from the region is probably the Kimberley point, named after a distinctive bifacially flaked lithic technology from the northwest part of Australia. Beginning in the 1800s, Kimberley points were commonly manufactured from bottle glass (Fig. 1) as well as other foreign materials such as porcelain insulators. Kimberley points were virtuoso performances, signaling the high degree of skill of the knapper (the person who shapes the stone). Shifts in material could have important social ramifications. For example, access to foreign materials meant that young men no longer had to rely on elder males who held the knowledge of the best stone sources. This resulted in shifts in some of the gendered power dynamics in Aboriginal societies. In interactions with foreigners, Kimberley points became valued commodities in the emerging tourist art trade, as artifacts of “authentic” Aboriginal masculinity that could be purchased and displayed by Westerners (Harrison, 2002, 2006).

Elsewhere in Australia, more humble scrapers and flakes played an equally important role in

Worked Glass Artefacts in Australia and the Pacific, Fig. 1

Australian Kimberley points made from bottle glass (Courtesy of the Australian Museum, inventory numbers E020554, above, and E078725, below, photograph by the author)

interactions between Europeans and Aboriginal people. At Port Essington, an early colonial fort in northern Australia, a significant proportion of the recovered glass artifacts (roughly 18 %) were identified as likely to have been worked by local Aboriginal people. The area around Port Essington is thought to have been poor in terms of natural stone sources, so bottle glass would have been a welcome raw material that could be scavenged from the European midden. Animal bones from the site include a number of native species, and it has been suggested that local people were hunting to provision the fort at Port Essington in exchange for trade goods, an interaction that may have been facilitated by the availability and use of glass for Aboriginal tools (Allen, 2008, pp. 79–88, 103).

Worked glass tools have been found in other Aboriginal contexts in Australia, including abandoned mining camps, pastoral sites where Aboriginal people worked as ranch hands, and Aboriginal households in Tasmania (Gibbs & Harrison, 2008; Harrison, 2004, pp. 128–137; Murray, 2010, p. 317). These assemblages show a common tendency to use the bottle base as a core from which pressure-flaked tools could be obtained. Aboriginal people sometimes scavenged the middens of long-abandoned sites for bottle glass, selectively carrying off bottle bases to particular activity areas where they could be processed into tools. Worked glass reveals the ways that Aboriginal people incorporated foreign materials into their daily lives,

appropriating mass-produced objects while maintaining their own technological skills and habits.

Elsewhere in the Pacific, studies of worked glass have been more limited. This is not because the artifacts are necessarily less common there. Rather, it reflects a lack of systematic study of this kind of material in the region. Future archaeological investigations of colonial sites in the Pacific should keep an eye out for worked glass, which is known from ethnohistoric and archaeological sources. One systematic study of worked glass tools that has been carried out in Polynesia analyzed an assemblage collected in the former leprosy settlement at Kalawao, Moloka'i, Hawaii. The worked glass tools date to between the 1860s and the 1920s. The tool form was quite variable (Fig. 2). Some artifacts were adaptations of traditional Hawaiian forms to the new raw materials, but other forms, such as those using bottle bases and necks to provide smooth handles, are interpreted to represent experimentation and innovation with this kind of technology. In part, this may relate to the situation of the people who were exiled to Kalawao because of their diagnosis of leprosy. Leprosy reduces feeling in the extremities, so when handling sharp objects, it would have been important to have a large, smooth surface to grasp (Flexner & Morgan, 2013).

Worked glass is an important artifact type for understanding colonial interactions in Australia and the South Pacific. This kind of technology

Worked Glass Artefacts in Australia and the Pacific, Fig. 2 A sample of glass artifacts from Kalawao, Moloka'i, Hawaii, interpreted as scrapers with evidence of retouch or use

could be an important form for technological persistence among indigenous people, using traditional local techniques in an introduced material medium, which was often tied up intimately with expressions of identity. At the same time, worked glass could also be a medium for innovation and cultural change. Archaeologists and anthropologists often discuss the importance of objects as facilitators of cross-cultural interactions. Worked glass is one type of object that can be informative in discussions about technology, identity, and indigeneity during a crucial period of regional history.

Wound Healing in Ancient Egypt

Hedvig Györy

Representations of injuries are relatively infrequent in ancient Egypt. However, the accuracy in the depiction of accidents in the joiner's shop drawn on the wall of the tomb of Ipui in Deir el-Medineh, and the representations of the battle of Qades in Abu Simbel, Luxor and Ramesseum temple, reveal exceptional medical details and the consequences of specific injuries. The exact identification of injuries on the battle scenes is possible in two-thirds to three-fourths of the injured (only Hittite) soldiers. Most of them were inflicted on the chest and abdomen, or neck and head, respectively, these being the largest targets in bow-and-arrow warfare or in hand-to-hand fighting. For instance, a 'decelebrate rigidity' is shown in a Hittite soldier struck by an arrow on the top of his head, or a haematoma (accumulation of blood) is shown deep in the abdominal wall caused by an arrow entering another Hittite soldier's right lower-chest or abdomen below the rib cage. An examination of skeletons show that arrowheads severed most of the spinal cord, resulting in instant paralysis of the body below the neck (In the text, the following abbreviations are used for two medical papyri: Eb is Ebers papyrus and SM is Edwin Smith papyrus).

Types of Wounds

We can differentiate several types of wounds depending on their characteristic look, origin or severity. The same is true for ancient Egyptians. Moreover, medical papyri, especially the Edwin Smith papyrus, are very accurate and detailed in the description of various types of injuries and their treatments. They tell us that the healer was able to characterise the most important types of injuries, impressive even by today's standards.

They differentiated various types of swellings, wounds, fractures and joint injuries.

The general word for an injury, where the protective function of the skin was disturbed or hurt, i.e., a wound, is *wbn.w*. Without any explanation it means the commonest form of injury, the rupture of the soft tissue overlying the bone and leaving a constricted orifice. Beside this simple form, they spoke also about a *wbn.w n kft*, (a gaping wound) describing an open wound with a well-defined gash as, for instance, in Sm 28, where the most important clinical sign for an open oesophagus, drinking water regurgitating through the wound, is mentioned. The axillary could also be open (Sm 47). Another type of *wbn.w* could be *wbn.w sd (sg)*, (a wound smashing (sg) or contusion), or *wbn.w jsp (r3-r)*, [a wound cutting (through)]. Another description of wound, known only from the Smith papyrus, is *wbn.w jsdb (r)*, [a wound piercing (to)], which seems to be nearly synonymous with *wbn.w 'r (n)*, [a wound penetrating (to)]. According to the examples we have, the penetration reached a solid body part as bone, while the piercing came through into a void. For a simple perforation the common word was *thm*. Finally, in pEbers 877c we find the *wbn.w shm*, (a crushing wound), laceration and rupture, and in pEbers 494 *wbn.w n wbd.t* (burn wound), although for designating this last type it was enough to write *wbd.t* – (burn) alone, or to give the word for the actual phase of its development. Ancient Egyptians differentiated various types of fractures. Beside the *hsh* – simple, open fracture – there was the closed *sd* fracture, where the bone was broken in two inside the body, or the commuted compound or impacted *psn* fracture, where the bone was broken in several places. The above-mentioned *thm* and *shm* could also occur below the skin. As a diagnostic clinical sign of fracture, *nhbbh*, meaning, in all probability, ‘crepitation’ [the noise made by rubbing together the ends of a fractured bone], is mentioned.

Treatment

During the repair of any type of wound, the practitioner has to face three basic factors: pain,

bleeding and infection. The ancient Egyptians realised only two of them, since they regarded infection as part of the recovery process. The most common complaints, swelling and fever indicate that wounds were often infected.

Interestingly, they never mention anaesthesia for use in surgical interventions although pain-killing must have been an important part of the repair procedure. The possibility of anaesthesia was there because we know that they collected rush, which can be used as a narcotic, that they knew very well the effects of alcohol, that they cultivated mandrake and poppy from the New Kingdom on, and that the medical papyri reveal a knowledge of hyoscyamus [henbane, a genus of poisonous herbs] and scopolamine as well. Their use of analgesia was thus theoretically possible, either in the form of a type of food or concoction, and their use as hypnotic agents might also be hypothetically suggested. The only words, however, which might hint at anaesthesia accompanying the Old Kingdom circumcision scene where the use of local anaesthesia can be deduced from a promise to make it *ndm* – ‘sweet, agreeable’, when the region is rubbed with a piece of stone. Some consider that water was mixed with vinegar over Memphite limestone, resulting in the formation of carbon dioxide, which may have had an analgesic effect; the process would then resemble today’s cryo-analgesia.

Ancient practitioners were more deeply concerned with arresting haemorrhages, since the *mtw* (Eb. 871), tumours (Eb. 875) and wounds were susceptible to bleeding.

Medical Protocol

In preparation for medical treatment in ancient Egypt a medical protocol was first issued by describing the symptoms, making a diagnosis and giving the form of treatment. This process was usually followed by the medicine man, who was usually a physician or probably a priest of Sachmet.

Diagnosis could be divided into three categories: (1) “an ailment, which I will treat”; (2) “an

ailment which I will contend with”; (3) “an ailment not to be treated”. The main wound repairing methods were bandaging with an ointment or poultice, scorching (Eb. 876, Eb. 872) and surgery. In doubtful cases, enforced bedrest and normal diet were often recommended to the patient until he reached the decisive moment when the healer could give either a positive or negative prognosis. At the end of the treatment sometimes the verdict was also given as (a) “until he recovers”; (b) “until the period of his injury passes” by; (c) “until you know that he has reached decisive point”.

Relatively fewer examples are given for incurable ailments. Only 5 out of 48 cases in the Smith papyrus, and a few in the tumour section of the Ebers papyrus, as Eb. 874, may be leprosy, or Eb. 873, a possible cavernous haemangioma, or a twisted vascular swelling forming knot (in this case, however, the *mtw* should be straightened). The first two steps in Eb. 877 are still unidentified, although cancer, cutaneous leprosy, bubonic plague or neurofibromatosis has already been suggested. In the last step in Eb. 876, the ball-shaped extensions have tentatively been identified by Regöly-Mérei as varicosities.

The cause of wounds can be varied. They are most often trauma by accident or battle, blows or knocks, scratching or scraping, bites, burns or a symptom or stage of an illness. The preferred treatment was drug therapy accompanied by bandages, which was supplemented in severe cases by small surgical interventions. Some mechanical treatments are also known.

Surgery also took place sometimes for religious (circumcision) or aesthetical reasons (ear or nose restitution) and prosthetic surgery was also known, although not all that often.

Types of bites, such as those from crocodiles (Eb. 436, H 239-40, 243), lions (H 244) and humans (Eb 432-435, H 21), were treated like any other wound, preferably by applying fresh meat on the first day and, subsequently, honey, wax and oil or grease as in Eb. 435 or by using other herbal remedies, occasionally with the addition of some animal ingredients. Snakebites, however, were treated differently, and by different medicine men, mainly by the snake-

charmer priest of Selket, because of the venom inflicted by the bite into the body. Tumours were well differentiated. Several sorts of tumours, abscesses, cysts, swellings, and boils (*hnhn.t*, *ʒ.t*, *sft*, *nw.t*, *šfw.t*, *hsd*, *twʒ.w*, *bsj*, *hmʒ*, *sh*, *bnw.t*, *wnm-snf*) are mentioned mostly in the Ebers, Hearst and Berlin papyri, with very brief medical instructions. These were treated by the same methods as wounds caused by mechanical injuries.

In the Ebers papyrus there is a complete book on wounds originating in burns: 482–509. No. 482 lists a sequence of remedies which, it says, should be applied consecutively. In other cases, remedies applying an ointment or bandage are always the same.

Methods

Drug Therapy

Egyptian drug therapy can be regarded as having evolved from a system rooted in magic that developed from empirical observations. Sometimes a sequential approach was used (Eb 522). In the 182 cases given in the Smith, Ebers, Berlin, Hearst and Ramesseum III papyri regarding wound repair, almost 130 types of materia medica were used. All were applied externally. More than 60 % of them were herbal remedies; the remaining types were mineral or substances originating from animals (both in about the same degree), with a few undetermined components. The only human remedy was urine.

Very often (in every sixth case), fresh meat was applied to a wound on the first day as an efficient haemostatic and mechanical agent. It was bound on the wound on the first day only, and was usually followed by the application of a lint saturated with ointment composed of grease and honey, also bound on. In specific cases, many other ointments and poultices were also applied (e.g., Eb 510-42). In other cases the treatment started with these materials. Almost 80 % of the prescriptions contained oil or grease in either the form of *mrh.t* or *d*, both prepared from various plants or animals, closing off the wound from air and introducing some minerals or vitamins into

the injured tissues. In almost half of the prescriptions honey was used, which can be beneficial as a wound dressing because it inhibits the growth of micro-organisms and is hygroscopic, thus attracting an abundant secretion of leukocytes and antibodies. Taking into account that the wax, which was also frequently mentioned in these cases, must have also contained some honey, its use was as popular among Egyptian drugs in wound healing as oil or grease.

d3r.t was often used (ca. 25 %), probably because of a disinfectant effect; this has been determined from the analysis of its use in various ancient Egyptian prescriptions. Unfortunately, the identification is not fully resolved: colocynth (The colocynth is the light spongy pulp of the fruit of the bitter cucumber (*Citrullus*, or *Cucumis*, *colocynthis*), an Asiatic plant allied to the watermelon. It comes in white balls, is intensely bitter and a powerful cathartic. Also called bitter apple, bitter cucumber, bitter gourd) and carob are suggested, although the last one seems to be more probable. Besides these basic medicaments, some others are also characteristic. Typical poultice materials were beans, peas, leeks, a sort of fibre (*dbj.t*), faience powder, *bsn*- clay, *wš*-mineral, *jmrw* – eventually gypsum or plaster, and linen (both the usual colour and *jrtj.w* - a red one).

Several other materials were used for their antibiotic, antiseptic, astringent, rubefacient (for internal pain), antiphlogistic (counteracting inflammation), analgesic, fever reducing, hygroscopic or wound sealing effects, or because they could contribute to the formation or development of the epithelium. Most of them are listed, but infrequently. Only a few are common: incense, salt, acacia, sycamore, barley, millet, faeces of various animals, Christ thorn, celery, cumin and a few unidentified ones. Some of the materials used only rarely might also be very effective. This can be stated for instance for the willow (*ṯrt*) having salicyl as its analgesic, fever reducer, anti-inflammatory effects, and being also anti-rheumatoid. It is, however, only mentioned in three prescriptions. Another such component is onion, listed only once, but being a good anti-inflammatory and very effective against

staphylococci, streptococci and some sorts of dermatomycosis [fungal infections of the skin].

The question can be raised, however, how often a certain prescription was used, as we can surely attest that the medical knowledge of ancient Egyptians was slowly but continually developing, incorporating new methods and materials in their papyri, although they continued to practice medicine as they had earlier times. One of these new materials was also the willow.

Mechanical Treatment

Treatment for Joints

Dislocations (*wnh*) and sprains (*nrrw.t*) were treated. In the tomb of Ipuj in Deir el-Medineh, there is a picture of industrial accidents. Among them the use of Kochers method for dislocated shoulders (Kochers method of reduction involves bending the elbow to 90°. The arm is slowly rotated 75° laterally, then the point of the elbow is lifted forwards, and finally the arm is rotated medially) can be clearly discerned. Other methods are described in the Smith papyrus, for instance, treatment for the dislocation of a jaw (Sm 25). For neurological complications resulting from the dislocation of a cervical vertebra, the inability to move the limbs, priapism, urinary incontinence, and intestinal dilatation with gas (paralytic ileus) are mentioned (Sm 31). In another case, a positive Lasague sign is described, i.e. pain due to a sprain of the vertebral column when the legs are extended (Sm 48), which indicates a prolapsed lumbar intervertebral disc with nerve involvement.

Bandages

For drawing together a gaping wound they applied strips of adhesive plaster, putting them on both sides of the wound (Sm 10, 27). Splints could be used for administering medicament into the mouth, as it could be held open with them. The same supporting use is attested at nose and ear operations. The common application of splints was for fractures. Wounds were usually bandaged after ointment was put on them, or the bandage was saturated with it. The linen for bandaging (Sm 2, 9, 10, 27, 47) varied in texture from

the finest silk-like gauze to a canvas-like coarseness. Ancient Egyptians had special knowledge in this field, which was explained in a specific book, as a note in the Smith papyrus says. The skill was first taught for the bandaging of mummies.

Treatment for Fractures

Based on many relatively good healing settings, we can assume that ancient Egyptian bone setting was advanced. Among the skeletal remains from ancient Egypt, there are innumerable completely healed limbs with good realignment of the bone, but most other bone settings often show gross shortening and misalignment. Since fractures of the femoral bones often healed without complication, it may indicate, on the one hand, that the virulence and incidence of pyogenic [producing pus] pathogens was lower than they are today, although their existence is proved by the frequency of osteomyelitis. On the other hand, based on the skeletal remains of pyramid workers and other Egyptians, it is obvious that fractured limbs were splinted using an advanced technique. Cleverly, if only one of the bones of the lower leg or forearm was broken, the remaining intact bone served as a splint for the broken one, and healing was satisfactory. In instances where the damage was so severe, amputation was an alternative course of action.

The standard procedure for the reduction of fracture was traction (Sm 12, 35, 36). And, indeed, many humeri set in splint remained. The first procedure was, after realigning the broken limb, to set it either with a splint wrapped in bandages, or encased in a healing poultice-cast that could be made of various (often unidentified) materials, as, for instance, (to mention some known substances) cow's milk mixed with barley (H 219) or acacia leaves bound together using gum and water (H 223). For reducing a fracture of the clavicle (Sm 35), the ancient Egyptians also used a modern method, first described among Greek physicians by Hippocrates, by stretching the patient 'on his back with a folded cloth between the shoulder blades' and pulling 'on his two shoulders until the fracture falls into position'. Among the neurological

complications, as in the case of an impacted fracture of the cervical vertebrae (Sm 33), aphasia, unconsciousness and tetraplegia, are mentioned.

Surgical Processes

- Wounds were often surgically treated by suturing with *jdr* stitching (Sm. 3, 10, 14, 23, 26, 28, 47). The Smith papyrus has the first mention in history of 'stitching' a wound. Other wounds were not sutured, but kept open.
- The *thn* – piercing with the *hmm* instrument – was prescribed for opening the ascites [fluid in the abdomen] in Eb 865. Regarding the only surgical procedures for burns, Eb 504 speaks about opening a blister, this time with a sharp thorn.
- Sandwiched between two pharmaceutical prescriptions, also for a blister in Eb. 501, an incision is suggested, but, as usual, without any details.
- The *d w-^c* 'knife-treatment', meaning, probably, excision, was fairly popular, as the many prescriptions show: Eb. 866 for a vascular tumour (haemangioma?), Eb. 867 for a presumably subcutaneous lipoma, Eb. 868 for a possible sebaceous swelling with metathesis (*3t nt s3*), Eb. 869 for an abscess, Eb. 870 for a swelling. The identification of the latter has several possibilities, such as a dermoid cyst lined with skin appendages, pilonidal sinus located in the midline or sebaceous cyst of the scalp, as, for instance, atheroma, Eb. 871 for an abscess in the axillary lymph glands.
- Sometimes, the *d w-^c* 'knife-treatment' was applied with a heated (*sšmm*) knife as in Eb. 872 for a probable haemangioma.
- In some cases 'fire' is mentioned, treated 'with the *s3-hmm* (firebolt?-man)'s treatment. This scorching was used in the case of the skin-like flesh protrusion in Eb 863 or that of the (umbilical or epigastric?) hernia in Eb 864.
- The method was applied according to the state of the cause, as in the first two cases of Eb. 876, where the tumour was eliminated either by excision or by scorching fitted to its state.

In all the above cases, procedures are not described and thus nothing definite is known. The only complex and detailed surgical process is given in the Ebers papyrus (Eb. 875)-with various knife and forceps devices-and is, in all probability, the month-long treatment for dracunculiasis (which may be the origin of the medical emblem with snakes), and thus a very atypical surgical invention.

Skull Repair

According to the Edwin Smith papyrus, the ancient Egyptians recognised brain disorders and performed skull repair. They were also the first in the history of medicine to identify the inner parts of the cranium. They also provided vivid descriptions of the brain and cerebrospinal fluid. Parallel to the development of weapons, the number of head injuries increased, thus making the discussion of the many cranial injuries in the Smith surgical treatise fully understandable. The dominant factor in healing, however, seems to be the *vis mediatrix naturae*, the expectant healing power of nature. It is also manifest by the signs of treatment on heads with cranial injuries found by Elliot Smith, Wood Jones, Courville, and recently, Nerlich.

The ability to recognise the classic sign of a base fracture in the skull, i.e. bleeding from the nostrils and ears (Sm 4-5, 7-8, 17, 21-22), or the basic sign of meningeal irritation, i.e. the inability to flex the neck to the breast (Sm 3-5, 7), indicates a sound basic medical understanding. And, indeed, pathological descriptions give clues to the identification of cases, like classic meningitis in Sm 3 or cerebral prolapse and nuclear rigidity in Sm 6. In Sm 7, a complex case scenario is given dealing with a fracture at the base of the skull. First, trismus and meningeal irritation (cured by palliating treatment with an unknown hot material, allowing the patient to be able to open his mouth), then infection of the wound causing tetanus is diagnosed, again treated by palliative treatment with *md3.t* - 'wooden chisel' and tigernut drink (*w'h*), since recovery was hopeless. The Smith papyrus also discusses a *contracoup* case with a pulsating

swelling protruding through the cranial fracture (Sm 8), where, besides the symptoms of the eyes looking in the direction of the affected side, the ears and nose are bleeding and nuclear rigidity with a hemiplegia on the injured side is documented.

Snakebite

According to the Brooklyn Herpetological Papyrus, snakes and the effect of their bites were accurately identified, and their bites treated with rational medical care. The treatments comprised the application of bandages with salt and natron, both being anti-agglutinant and anti-hemolytic, thus hindering the absorption of the venom; drinking of emetic remedies with various drugs to get rid of venom by vomiting; fumigation as adjuvant; magical spells for general and specific divine help and/or the *dw*-^c-knife-treatment and the *tštš* incision in the swelling. For drug therapy many earlier, not medically attested, substances were used, which may be explained by the 30th Dynasty date of the papyrus or by our missing knowledge of empirical snakebite treatment, but eventually by both of them.

The simple cut (*dw*-^c) was applied there twice, in the case of a 'male viper' (Br. 31) and of a uraeus/cobra (Br. 32); the wound is attributed to Seth and the prognosis is positive in both cases. The action is not specified, and, for the first case, there is nothing else to do. In the second case, however, the knife treatment is preceded by a remedy ('every thing for ...') with a missing part, which is thought to be by Sauneron 'emetics'). These two procedures resulted in vomiting, thus saving the patient's life. The word *tštš* originally meant 'crush'; in these cases, however, the knife determinative finishes the hieroglyphs. Thus, here the '*tštš* with many cuts' means, in all probability, the cutting of the area of the bite into pieces by a knife, applied to the bite swelling of any type of serpent (Br. 72a) or, specifically, to that of an unidentified cobra(?) 'male snake' (Br. 81). The next step was, however, the bandaging of the wound with salt or natron, or, in the second case, a medicament with

the addition of incense, an unidentified liquid, and cobra blood. The latter one, in addition to the venom, also contains the antitoxins.

Surgical Devices

We do not know very much about medical implements. The earliest tools come from the tomb of Qar of the 6th Dynasty, including 40 scalpels and tweezers as well as other medical tools whose purposes are still unknown.

For cutting the flesh they used knives of particular shapes and sizes. Various ancient Egyptian names are also known, such as *ds*, *hpt*, *s3s*, *hmm*(?) or *swt*. There was also a peculiar fish-tailed knife, called *ps3-kf*, used for cutting the umbilical cord after delivery. In the beginning the knife was a ‘disposable’ stone, most likely made of flint or obsidian, which was still used for cutting up dead bodies for mummification in the first century AD (Diod. I. 91) or blades fashioned from reed stems. However, cuttings on the body were made from the New Kingdom on, also with a metal knife. This innovation led to a new procedure: the blade was heated until it was red hot before an incision was made so that the knife both cut and sealed at the same time.

If a bone broke, bark or cartonnage cases padded with vegetable fibre or linen for securing the injured member by splints might be used, but Eliot Smith also mentions splints made of reeds connected by a linen band.

For taking out pieces of bones or any other foreign bodies, tools such as hooks and forceps were used. There was also a pair of small leather forceps, called *hnw(h)*. For discarding pus or other amorphous formations, tweezers or spoons and spatulas or vegetable ‘knives’ (*sw* = bulrush) were used. Other plants were used in other ways; for instance, the thorn of an acacia was used for cutting up blisters (Eb. 504 = L 52 = L56).

For cauterising there was the *d3* – ‘fire drill’ and sometimes heated metal cauteries. For closing open wounds, various types of bandages (*h3yt*, *s3d*) or needles for suturing by *jdr* stitching were employed. Linen strips coated on one side

with a gummy substance were used, for instance, as strips of adhesive plaster (*3wy*). They had a sort of cotton wool made of fibres of the plant *dhj.t*, which was soaked in drugs (Sm 28) and enclosed by linen bandages (*s3d*). To prevent the dislocation or slipping of the bandage, they applied a gummy substance or varnish taken from embalmers. A wedge covered with layers of cloth is described in Smith 7 for use in prying open the jaw.

Medical devices seem to be varied and fairly specialised, each used according to its function or to the requirements of a particular stage of the operation. Their refinement was, however, primitive, although the technical skill existed to make complex instruments, as we know that some cosmetic devices are astonishingly complex and of high quality. The repertoire, naturally, continually changed and developed. The state of our current source material, however, does not allow us to deduce details. At the temple of Kom Ombo, a box of instruments for a general practitioner, carved into the outer corridor wall and originating from the Roman Period, contains 37 instruments, identified as metal shears, knives, saws, suction cups, probes, a saw, tweezers, pincers, small bags, retractors, a small scale, lances, specula, chisel, dental or cleaning tools, spatulas and spoons, together with some objects having connections with magic. The ensemble presents a good example of the last period of Egyptian medical praxis, when Pharaonic Egyptian and Graeco-Roman medicine were completely fused.

Mythological Background

The medical papyri point to the fact that pernicious beings could enter and leave the organism through the openings of the body and thus harm people. From the Egyptian medical perspective, the wound was also an opening. Thus wound management had to be twofold. The first task was to repair the harm already occurred, by closing the opening and repelling the demons who had entered. Prevention was essential too, to assure the defence of this gate by magical rites and material feared by these illness-causing

Wound Healing in Ancient Egypt,

Fig. 1 Detail from the Smith Surgical papyrus (Source: Breasted 1930)

intruders. Seth often personified their negative power. The association of Seth with wounds was close, whether the wound was received in battle or as a consequence of the mythical fight between Horus and Seth for the succession to the throne of Osiris. According to this concept, any illness could only be healed with religious rites.

Material in connection with a plant or an animal might dispose some magical power and be a device through which people could get in contact with the gods. And the same is true for minerals. Thus any medical material could also express the protective role of a deity itself. This view is the most manifested in 'magical' components of the prescriptions. But even their choice was based with all probability on long empirical observations. Many of the materials are still (may be forever) unknown for us, but most of the identified ones have proved to be reasonably explained, and are appropriate in terms of their effect. The explanation of their effectiveness could only be given at that time, however, by mythological-theological reasoning.

Various material combinations could be used for seemingly the same type or state of illness or

health, having the same or similar effect. There were several routes of drug administration, with a wide range of formation for use. They were usually determined by the choice of ingredients applied both for their physical-chemical properties and magical assumptions. The sycamore was, for instance, the tree of Hathor, Nut or Isis, the Christ thorn that of Thot of Pnubis, malachite was the mineral of Hathor, the donkey belonged to the god Seth, excrement was disgusting even for illness-demons, the *s3-wr* resin bore in its name ('great of magic') its magical connotation. For patients who were wounded, bandages were also used as magical devices. They were traps, so that invisible beings could be kept off or removed.

Another way of making a treatment more effective was religious-magical rite. Similar to cases in the London papyrus (15–21, 46–48, 53–61) and also among the Ebers papyrus prescriptions (482–500), magic spells had to be cast, referring to Horus having been burnt in the desert. According to the incantation of Eb. 499, which had to be recited with mother's milk, Isis used 'water in her mouth' and 'Nile springing between her thighs'. Then mother's milk, gum and ram fur

(having a high cholesterol content) were put on the burnt wound.

The mythological background worked as a psychological support as well, which recent studies have shown can reduce pain perioperatively and increase patient's satisfaction (Figs. 1, 2, and 3).

Writing

Martha J. Macri

Writing ranks among the most important of human inventions. Yet it is only one of many forms of visual communication. Others include sign language, dance, and bodily adornment, notched tally marks, stones signposts, as well as the more complex painting and carving of complex narrative scenes. Some of these are, like writing, ways of recording information, that is, of creating a more or less permanent record available to persons outside the immediate time or space. All visual communication depends upon at least minimal familiarity with the cultural conventions of those producing it. Specifically, writing is a technique for recording human speech. Today speech, both the aural and the visual aspects of it, can be recorded and reproduced electronically. However, prior to the invention of the wax cylinder phonograph, human language could only be recorded, however imperfectly, in written texts.

Writing is an entirely arbitrary system in which each symbol in a script has an agreed upon value. The symbols may or may not have any association with a real world object. Thus, all scripts must be learned within the context of a specific culture, and within the context of a specific speech community. Although the Chinese script can be read by speakers of a number of different languages, the conventions of the script and the way it relates to a speaker’s own language must be painstakingly memorized.

Writing seems to have been invented at least three times in human history: in Mesopotamia, in China, and in Mesoamerica. It may be that there were other independent inventions, or it may be that all the other writing systems have been the result of stimulus diffusion – the spread of a good idea. An evolutionary theory of writing sees a development from pictures to complex symbol systems to scripts with word signs to phonetic (sound based) writing systems.

Logographic scripts (ones in which a picture or symbol represents a specific word) make use of rebuses, that is, of using a picture of an object to represent a word that sounds like the object pictured. Such a script is always language specific. For example, using the picture of a honey bee for the verb *to be* works only in English. Logographic scripts nearly always include additional elements to clarify meaning (semantic determinatives) or to indicate the sound of a word (phonetic complements). Ancient Egyptians had sets of consonant signs indicating one or two or three consonants, as well as hundreds of logographic signs and semantic determinatives. Other examples of logographic scripts are Sumerian, Chinese, Naxi (southern China), and Mi'kmaq (Canadian maritime provinces).

The next step in an evolutionary theory of writing is the addition of a significant phonetic component. In phonetic scripts most signs refer not to words, but simply to sounds. Of phonetic systems there are two types: syllabaries and alphabets. A syllable is composed of a vowel and any consonants that immediately precede or follow it. In practice, in most syllabic scripts, each sign represents a simple consonant-vowel combination. There are, for example, individual signs for *pa*, *pe*, *pi*, *po*, and *pu* instead of a single symbol for the sound *p* and symbols for each vowel. Syllabic systems often include a set of logographic signs (such as the *kanji* component of Korean and Japanese), and may have one or two symbols for a single consonant (in Japanese there is a symbol for *n*, in Cherokee a symbol for *s*). Although early students of writing considered syllabaries to be merely a step toward the culmination of the alphabet, syllabic systems have had a long history of success. Japanese, Linear B, Akkadian, West African scripts, and Cherokee are only a few examples.

In contrast to multiple inventions of syllabic scripts, the alphabet seems to have been invented only once. Certainly there are hundreds of distinctive alphabetic scripts, but the history of each one can be traced from a single origin in the Mediterranean region some 3,500 years ago. In alphabetic systems, each sign represents a single

sound – a single consonant or vowel (the earliest alphabets were largely consonantal systems). The Proto-Sinaitic, Ugaritic, and Phoenician scripts are the immediate ancestors of the Greek and Roman alphabets. Alphabets have an advantage for languages with consonant clusters such as English. The word *split*, for example, in a syllabary would have to be written with four syllabic signs: *si-pi-li-ti*, suggesting the presence of more vowels than the word has. The sequence of syllabic signs could also spell *spilt*, or any of a variety of nonsense words. Alphabetic systems generally include at least a few logographic symbols, such as the symbols for numbers.

Any script with a history – one in use longer than a single generation, or used for more than one language or one dialect – suffers from the effects of standardization and carries a baggage of archaic spellings. *Aunt* and *ant* may or may not be pronounced the same. *Beau* and *bow*, *bough* and *bow* reflect language history, and show clearly that English writing is not a purely phonetic system. Standardized spellings are much easier to read than technical transcriptions, in which linguists using a system such as the IPA, the International Phonetic Alphabet, try to capture the precise details of a specific utterance.

Although no script is ever a pure example of the above categories, each category differs in the usual number of total signs. Counting the number of individual signs can sometimes suggest the nature of an unknown script. Logographic systems contain the most signs, sometimes numbering in the thousands. Syllabic systems require only as many signs as there are consonant + vowel syllables in a language, usually in the range of 40–150 signs. Mixed logographic-phonetic scripts can range from hundreds into the thousands. Alphabets have the fewest – only enough to represent the sounds of a particular language. Only 13 letters are needed to write the Hawaiian language, compared with 24 symbols in the Germanic runic script and 44 for Cyrillic. The total number of signs in an alphabet does not necessarily match the number of distinctive sounds in a language. The alphabet used for English has only seven vowel letters (*a*, *e*, *i*, *o*, *u*, *w*, and *w*) that are used alone or in various

combinations to represent at least 12 distinct vowel sounds.

Another way that script types differ is in their longevity. Two of the best known logographic scripts, Chinese and Egyptian have had far longer life spans than the alphabet. An identifiable Chinese script was functional at least by 1200 BCE, and continues in use by millions of people today. Egyptian hieroglyphic writing ceased by the tenth century CE, but has a history of nearly 4,000 years. Akkadian in Mesopotamia was used for over 2,000 years. Syllabaries seem to have briefer lives. Linear B in Mycenaean Greece was used for about 200 years. The two syllabic components of the Japanese script, *hiragana* and *katakana*, are slightly over a 1,000 years old, developed by the eighth and ninth centuries CE, respectively. The Cherokee syllabary dates only from 1820. What of the alphabet? Probably dating no earlier than the first or second millennium BCE, its future seems promising. As a tool of the electronic age, the alphabet is a system adaptable to any language and is maximally efficient for keyboard use (this may be, however, because keyboards were invented for the alphabet).

One of the errors in an evolutionary theory of scripts is the notion that they become increasingly abstract, i.e., that over time scripts become more efficient, using fewer signs and simpler sign forms. Scripts with a heavy logographic component tend, however, to develop in the opposite direction, collecting baggage over time. Egyptian grew from 700 signs in Middle Egyptian (ca. 2000 BCE) to more than 5,000 signs by the fourth century CE. The ancient Maya script added hundreds of logographic signs over the 700 years of the Classic period (200–900 CE), while the core of syllabic signs grew at a much slower rate. Chinese characters have increased from 9,000 in the first century CE to about 60,000 by the end of the twentieth century, though today only about 2,400 are in common use.

These dramatic increases happened for several reasons. First, cultural and historical events bring additions to a script over time. This can be seen in the archaic spellings of many English words that

reflect pronunciations no longer used or used only in certain dialects. Second, although a purely alphabetic script is easier to learn and easier to write, logographic scripts, once mastered, can be read more rapidly. The debate of whether to teach English-speaking students to learn to read through phonics or through word recognition reflects the fact that even readers of alphabetic scripts make use of both its phonetic and logographic aspects. Third, universal literacy has not always been an ideal, and a difficult logographic script has sometimes been seen as a tool for limiting access to knowledge and prestige. Finally, and probably most significantly, languages rarely add a new sound to their sound inventory and rarely add new syllables. Words, however, are constantly being added. Since vocabulary is an open-ended component of language, any logographic script, one in which symbols represent words, is going to have to grow as new words come into use.

Some scripts owe their invention and development directly to contact between neighbors. One example is the Japanese writing system. Initially Chinese characters were used to approximate the Japanese language, then syllabic features were added to provide more specific phonetic information. Today the combination of *kanji* (Chinese logographs) with the *hiragana* and *katakana* syllabaries, make Japanese a script with one of the world's most arduous learning curves. Sumerian, a largely logographic system, was adopted by the Akkadians who like the Japanese added syllabic features, resulting in a mixed logographic-syllabic system that had a large syllabic component.

Some students of writing see the adoption of a logographic script by speakers of a foreign language as an explanation for the development of phonetic scripts. Foreign users reinterpret logographs that carry semantic and phonetic information as phonetic symbols representing sounds without the specific meaning, or as representing the same meaning but with the sounds it has in the new language, or they may invent phonetic signs to add phonetic information or grammatical detail. Such progressions can be seen in the development of Akkadian from

Sumerian writing, or of Japanese syllabaries, and the Korean script – both influenced by Chinese.

The vocabulary used to characterize a script varies from one to another. *Characters, hieroglyphs, glyphs, letters, symbols, icons, signs, and graphemes* all describe units of written language. The forms of the signs may be described as *pictographic, representational, linear, cuneiform, abstract, and geometric*. The organization of the units may be *columnar, clustered, horizontal (left to right or right to left), boustrophedon (back and forth, literally, as the ox plows)*. Within the texts themselves divisions between words, phrases, sentences, and larger units may be ignored or may be indicated by spaces, larger symbols (e.g., upper case letters), or a variety of punctuation conventions.

Language that is recorded in writing represents only a small subset of language that is spoken. Nearly every culture places specific limits on the kinds of information presented and on the manner of presentation. Commercial records, calendrical notations, prayers, magical spells, laws, census records, land deeds, court records, sacred and political histories, diaries, personal letters – these are among the earliest written materials. Novels, commercial advertising, and to-do lists are relatively more recent developments. The surviving examples of some ancient scripts are limited only to one or two genres.

Spoken language reflects an awareness of the speaker's audience, while written language may ultimately reach audiences never dreamed of. Written language tends to be more deliberate, generated at a much slower pace than speech. Nor does it have the meta-linguistic features that add dramatic force and subtle nuances to a speech act. Efforts to indicate variation in tempo, volume, and pitch (such as with underlining, boldface, accent marks, exclamation, or question marks) fall far short of the tools available to a speaker. Missing, too, are facial expressions, body posture, and hand gestures.

In contrast to recording language, there have developed a number of systems that approach writing, but do not fit the strictest definition of writing. Several of these hieroglyphic scripts are

or were, in fact, readable within the culture that produced them, but with no or with only minimal phonetic components they can have only uncertain meaning to the uninitiated. One example is the Mixtec writing known from eight pre-Columbian screenfold books. In these a complex iconography is tied to narrative images recording sequences of historical events and genealogies. Although the meaning is often clear, it is impossible to know exactly how the texts would have sounded when they were read – impossible to know precisely what words were associated with the images. Another example is the Naxi Dongba writing of southern China dating from the thirteenth century. This hieroglyphic script is still used and studied today. The meanings of the signs are complex, with minimal phonetic information indicated. Mixtec and Naxi represent yet another challenge to the evolutionary model. Rather than pictographic scripts always preceding true writing, some of them were created by cultures imitating neighboring scripts.

Also implied in the evolutionary theory of writing is a gradual development from picture signs to syllabic signs. Many books on the history of writing show charts of simple pictures for objects next to related but more abstract forms that exist in a particular script – the most common scripts pictured are Chinese, Akkadian, and sometimes even the Greek alphabet. However, direct evidence of this gradual development from pictures to a phonetic script is seldom available. An alternate scenario is that at some point in time one person, or a small group of persons, took an existing symbol system, and from it chose a set of signs to produce a phonetic system, usually a syllabary. We know that this happened with Sequoyah, the man who invented the Cherokee syllabary. History also tells us that this is what happened in the fifteenth century when King Sejong, or a committee created by him, developed the Korean *Han'gul* script. Because a phonetic script is a complex interdependent system it can only function when a complete set of phonetic signs are in place. For most scripts, this crucial moment of creation remains a conjecture.

Some have asserted that writing, specifically the alphabet, gave humans the ability to order and to classify information. Linguistic and cognitive anthropologists, however, have demonstrated repeatedly that complex categorization also exists in societies without writing. What then does writing contribute? Certainly it contributes a memory beyond the life span of a single person, knowledge that is independent of oral transmission. This enables an accumulation of knowledge across time and across cultures. Writing has given us detailed insight into earlier societies. Several languages, such as Sumerian, Hittite, Etruscan, and Tocharian, have no direct descendants, and are known only through their written texts.

This essay speaks about script types and script developments. For those who are interested in the variety of the world's scripts there are a number of excellent introductory texts, some generously illustrated. For example, see Coulmas (1989, 1999), DeFrancis (1989), Pope (1999), Robinson (1999, 2002), Rogers (2005), and Sampson (1990). One volume stands out for its quality and comprehensive coverage: *The World's Writing Systems*, Daniels and Bright (1996). Also excellent are the individual volumes of the *Reading the Past* series: Bonfante (1990), Chadwick (1987), Cook (1987), Davies (1987), Healey (1990), Houston (1989), Page (1987), and Walker (1987). Two dramatic stories of decipherment are Chadwick (1967) for Linear B and Coe (1999) for the Maya script. Boone (2000) and Boone and Mignolo (1994) offer enlightened discussions of nonphonetic systems. The potential of the as yet undeciphered Inca knotted *kipu* as a record of detailed information, perhaps including speech can be found in Urton (2003) and Quilter and Urton (2002).

Recent years have seen a growing number of websites, both about scripts in general, as well as sites devoted to a single script. Below are listed two general websites for writing systems, both with links to many other resources, and several sites relating to specific scripts or regions. Searching on the web for *writing systems*, or for any country, language, or script name will yield a large number of sites. Some of these are

sponsored by academic institutions, a few are commercial, and a few are sponsored by individuals. Their quality varies, though even sites with incomplete or nonstandard information often provide useful images.

Writing in China

Uta Lauer

The origin of a comprehensive writing system in China is a matter of debate. According to an ancient Chinese legend, writing was invented by the three mythical emperors between the twenty-ninth and the twenty-sixth centuries BCE. The earliest evidence for some kind of script is marks on pottery excavated from the Banpo site near Xi'an in Shanxi-province, dating from the Neolithic Age. Proof for a highly developed writing system comes from oracle bones (*jiagu wen*). Datable to around 1300 BCE, inscriptions on bovine, pig, deer shoulder blades or on turtle shell were used for divination. The elite of the Shang dynasty (sixteenth to eleventh century BCE) employed a question and answer model, through which those in power would ask a question, incise it into the bone, and the shaman or priest would drill holes into it, insert a piece of burning coal, interpret the cracks produced by the hot coal, and then write down the answer. About 2,000 different characters have been found on Shang oracle bones, but only half of these have so far been deciphered. Another form of surviving document is short texts cast on the inside of bronze vessels. There are numerous examples of late Shang inscriptions, typically rather short, whereas in the succeeding Zhou period (eleventh century BCE to ca. 771 BCE) inscriptions on bronze ritual vessels were considerably longer. The type of script employed during the late Zhou period was called great seal script (*dazhuan*).

One of the most important steps towards the development of a comprehensive writing system was the unification of the empire under the rule of emperor Qin Shihuang (r. 221–206 BCE) in 221 BCE. Under the jurisdiction of his Prime Minister Li Si, writing was standardised into the small seal script (*xiao zhuan*). This script comprised about 12,000 characters (*zi*). Today, small seal script is still in use on seals and in

advertisements. Seals had been made since at least the late Zhou period. They were used instead of a signature and served official, commercial, personal and literary purposes.

With the advent of the Western Han dynasty (206 BCE–9 CE) a new type of script came into use, clerical script (*lishu*). It was easier to write than the angular small seal script and thus more suitable for the ever-increasing amount of official, government related texts. Based on clerical script a kind of shorthand developed for less formal occasions like writing letters or jotting down notes. Literally translated into English it is called grass script (*caoshu*), but is also frequently referred to as draft script, running script or fully cursive script. To avoid confusion of technical terms, it is best to use the unambiguous Chinese terminology. During the Han dynasty, the potential of writing as a medium for artistic expression was fully recognised. It was then, that the art of calligraphy (*shufa*) was born. Another less abbreviated form which emerged from clerical script is semi-cursive script (*xingshu*).

During the fifth century, the last type of script was codified, regular script or standard script (*kaishu*), which is still in use today. After that, the evolution of the Chinese writing system was complete. This had a culturally unifying effect this had to a high degree. Chinese characters serve as a binding element, as an identification factor and as bearers of an uninterrupted tradition.

With the end of imperial rule and the founding of the Republic of China in 1912, a debate about the simplification of characters began. Some argued to abolish Chinese characters entirely and to replace them with a romanization system in order to promote literacy. Several reforms followed until finally in 1964 a list of simplified characters (*jianti zi*) was approved. Today simplified characters are used in the People's Republic of China whereas other countries which employ Chinese characters have maintained the complex characters (*fanti zi*).

In 1979 the government of the People's Republic of China adopted the Hanyu Pinyin system, a phonemic notation and transcription to Roman script. Pinyin is very useful as a cataloguing method and for writing Chinese on computers.

Essential for the development of the art of calligraphy was the material used for writing, namely the pliable brush, absorbent paper and ink. The earliest surviving documents written with a brush and ink on strips of ► [bamboo](#) date to the third and second centuries BCE. Already by the fifth century BCE silk was also in use as a writing ground. Silk existed in China since Neolithic times. Archaeological evidence shows that paper was being made from the first or second century BCE. Paper was much cheaper than silk, relatively easy to make and less cumbersome than bamboo strips. The availability of paper made possible the steady increase in writing throughout the empire. The earliest examples of ink are found in traces of writing dating to the fourteenth century BCE. Chinese ink is made from carbon, lampblack and glue which is then dried and moulded into the form of sticks or cakes. To obtain liquid ink, the ink stick has to be ground by hand on an inkstone with the addition of water. During the tenth century CE, writing equipment (brush, paper, ink and inkstone) came to be known as the “four treasures of the scholar's studio” (*wenfang si bao*).

Since ancient times, calligraphy belonged to the six liberal arts (*liu yi*) practised by the social elite of the country. When looking at a work of calligraphy, the viewer can relive the process of its creation. The writing speed, pressure, energy, any moment of hesitation remains visible on the paper. The flexible brush allows for an endless variation of stroke shapes. Soon, the styles of individual masters of calligraphy were canonized. For transmitting calligraphic styles, various copying methods and the formation of collections were important. Before the invention of printing in the Tang dynasty (618–906 CE), several techniques for copying were employed. Exact copying (*mu*) is basically a tracing technique. To make a free copy (*lin*) the original is placed next to the sheet of paper on which the calligrapher reproduces the work at his own speed. Essential for a wider circulation of calligraphy styles were ink rubbings. For this reproduction method, a copy of the original written in ink is pasted to a stone or wood surface and then meticulously engraved into the surface through the copying paper.

Then, a moistened paper is placed over the engraved calligraphy and pushed into the incised areas with a brush. Finally, a pad soaked in ink is dabbed over the surface. The background of such a rubbing appears black and the characters white.

All types of script are employed in calligraphy but semi-cursive script and grass script are the two most suitable for artistic expression. Among the most notable calligraphers are Wang Xizhi (307–365) and his son Wang Xianzhi (344–388), Yan Zhenqing (709–782), Huaisu (725–785), Su Shi (1036–1101), Huang Tingjian (1045–1105), Mi Fu (1051–1107), Zhao Mengfu (1254–1322), Wen Zhengming (1470–1559) and Dong Qichang (1555–1636). Since the fourth century CE records and art historical treatises on calligraphy exist. Calligraphy as the embodiment and a highlight of Chinese culture forms an important part of the imperial art collection.

In 1949, when the People's Republic of China was founded and the Guomindang defeated, the Guomindang took a substantial part of the former imperial art collection to Taiwan, where it was housed at the National Palace Museum Taipei. The remainder of the collection stayed at the Palace Museum Beijing. From the beginning of the twentieth century onwards, collectors outside Asia developed a keen interest in calligraphy. Private collections and museums in the USA and in Europe now own a number of representative works of Chinese calligraphy. Research at universities on the history and the aesthetics of the art of writing is particularly prominent at some major US universities and in Germany.

In China, both the practise and theory of calligraphy are taught at art academies. Exhibitions and competitions are held regularly. Some contemporary Chinese calligraphers have gained recognition outside Asia and their works are on display in museums. Calligraphy is an art that is very much alive. Not only is the tradition passed on but there is also experimental writing. Young artists explore and challenge the basic principles of writing in their works. The brush might be replaced by a neon light, ink by water, thus highlighting the act of writing and pointing towards the perishable material.

Writing in Egypt in Its Literary Context

William S. Arnett

Morgantown, WV, USA

The evolution of Egyptian writing (hieroglyphs) is traditionally dated to Dynasty 1 of ancient Egypt's Proto-Dynastic Period ca. 3100–3000 BCE. Until recently, priority of first place in the history of writing seemed to belong to the Sumerians of ancient Mesopotamia (now southern Iraq). However, the recent discovery of labels in tomb U-j at Abydos, Egypt, tomb of the Scorpion King, have provided evidence of writing in Egypt as early as 3250–3200 BCE. The earliest Egyptian attempts at writing consisted of postmarks, designs painted on jars, and of motifs carved on the surfaces of cosmetic slate palettes and other artifacts found in the graves of Predynastic Egyptians at a number of sites (ca. 4500–3000 BCE) and in temple deposits at Hierakonpolis. These examples were clearly precursors to the classical Egyptian hieroglyphs (Arnett, 1982; Casson, 1965, pp. 141–148; Elkins, 1999; Gardiner, 1978).

The hieroglyphs worked best on stone, although they were also written on papyrus and other materials. Papyrus was a parchment-like paper made from the reed plant of that name which once grew in abundance along the banks of the Nile River. It was the most common material used for official record keeping, correspondence, literary works, administrative documents, etc. For these purposes the Egyptians developed a more cursive style of writing. This occurred early in the development of hieroglyphs. Scholars call the earliest type of this writing hieratic (literally “priestly” writing), although it was not used exclusively by the priests. The scribes used lamp-black and wrote with reed pens when writing on papyrus and brushes when using wood and other materials such as ostraca (An ostrakon is a piece of pottery usually broken off from a vase or other earthenware vessel. In archaeology, ostraca may contain scratched in words or other forms of

writing which may give clues as to the time when the piece was used. The word is derived from Greek *ostrakon* meaning a shell or a shard of pottery used as a voting tablet. The plural of ostrakon is ostraca). Later, in the seventh century BCE, the Egyptians developed another even more cursive system that is known as demotic, or popular. Generally, both of these more rapid writing systems were written on papyrus (Figs. 1, 2, and 3).

The quantity of such examples of Egyptian proto-writing suggests that Egyptian writing may have evolved as early as (if not earlier

than) the Sumerian cuneiform system so prominent in Mesopotamia and much of the ancient Near East from ca. 3000–1000 BCE. It certainly proves that the Egyptians developed their own, unique writing system and that, if they borrowed anything from the Mesopotamians, it was the idea of writing (Arnett, 2004; Stiebing, 2003, pp. 110–112) (Fig. 4).

The earliest extant Proto-dynastic writings consist of numerous brief texts: funerary stelae, ivory labels and plaques, and a few official monuments and royal inscriptions found in situ at locations both in Egypt proper and in the

Sinai Peninsula. These early texts reveal a hieroglyphic writing system that was already fully developed, which led earlier scholars to believe that the Egyptians had borrowed their writing system from the outside world, presumably Mesopotamia. The earlier use by the Sumerians of “symbolic tokens and ideographic inscriptions” as means of the accounting and recording of quantities of products and livestock was assumed to have led to the development of the earliest phonetic writing system in ancient Sumer. But the labels of Tomb U-j at Abydos can be read phonetically and may be earlier than the earliest known Sumerian writing (Stiebing, 2003, pp. 112–113). We have evidence of early trade and cultural exchange between late Predynastic Egypt and southern Mesopotamia,

and it is highly likely that ideas as well as goods and materials were being exchanged. However, the fact remains that the two earliest systems of writing (Sumerian cuneiform and Egyptian hieroglyphs) use entirely different signs and methods of inscription. While some Mesopotamian writing has survived on stone artifacts, the majority was inscribed upon clay tablets. In Egypt, stone stelae and walls of tombs or temples, stone chips (or ostraca), pieces of wood, and papyrus paper (the use of which dates back to late Predynastic times) were the primary media upon which the Egyptians did their writing. It is more likely that writing evolved in both areas at about the same time (Mark, 1997; Wilkinson, 2001, pp. 150–182) (Fig. 5).

Writing in Egypt in Its Literary Context, Fig. 5 Ugaritic alphabet using cuneiform characters. From Ugarit (Ras Shamrah), Syria. Aleppo Museum (Photo by William S. Arnett. Used with his permission)

These early texts provide only minimal details of official political and historical events as well as the accomplishments of the owners of the tombs in which they were found (Breasted, 1906; Lewis, 2003; Lichtheim, 1975: (vol. 1) p. 3; Pritchard, 1955). It is the general consensus that Egyptian writing was initially created for the sole purpose of satisfying the needs of the state to record all of its administrative, political, economic, diplomatic, and military activities and transactions (Aldred, 1998).

King Lists constitute a genre of Egyptian writing reflecting the above – stated purposes. The earliest, the Palermo Stone, provides the names of kings of the Late Predynastic period through early Dynasty 5. Primarily a list of yearly events and statistics, the main value of this monument is in the ordering of kings by the length of reign and the listing of their achievements as well as recording annual Nile flood heights, a periodic census of men and livestock, and occasional references to public works projects and foreign trade. For instance, there is a reference to forty shiploads of cedar wood imported to Egypt in 1 year during the reign of Snefru of Dynasty 4 (Gardiner, 1978; St John, 2003; Wilkinson, 2000). Other important king lists include the Turin Canon, the lists of royal ancestors of Sety I and Ramses II at Abydos, the Royal List of Karnak, and the Royal List of Sakkarah (Clayton, 1994; Shaw, 2000) (Figs. 6 and 7).

But, according to Lichtheim, the “first major application” of Egyptian writing was in the omnipresent Offering Lists found in the tombs of the well-to-do Egyptians of the Old Kingdom (Figs. 8, 9, and 10).

Writing in Egypt in Its Literary Context, Fig. 6 Royal ancestors of Sety I and Ramses II (Dynasty 19). Royal cartouches on the walls of Sety's Temple dedicated to Osiris at Abydos. This scene shows part of the list of previous Egyptian Pharaohs (Photo by Jon Bodsworth. Used with his kind permission)

These offering lists consisted of the names of the tomb owners, their family members, a record of the offices and titles held by them, and an accounting of the funerary offerings they required. By Dynasty 5, the Offering List was shortened into a Prayer for Offerings (Breasted, 1906, Vol. 1, pp. 75–175; Lichtheim, 1975, p. 3) (Figs. 11, 12, and 13).

As a result, wall space was freed for the development of a descriptive narrative containing historical and autobiographical material which the Egyptian nobles (administrators, prophets, judges, “overseers of the King’s land,” viziers, architects, soldiers, scribes, priests, etc.) had written/sculpted/painted on the walls of their tombs and/or tomb chapels. These texts and accompanying illustrations provide us with portrayals of the tomb owner, his family, and his servants (Figs. 14, 15, 16, and 17).

These texts, also called “Biographies of the Nobles,” often contain gross exaggeration and considerable boastfulness, and were meant only for their family, priests, and the gods they were meant to impress. Their discovery in modern

Writing in Egypt in Its Literary Context, Fig. 7 Sety I and Ramses II. Seti I and his son Ramesses II offering praise to a list of royal ancestors. Temple of Sety I at Abydos (Photo by Jon Bodsworth. Used with his kind permission)

times has given historians access to important primary source material for the reconstruction of ancient Egyptian history. They provide us with glimpses of the public careers and achievements of the administrative, bureaucratic, and military personnel who served the kings throughout the history of Dynastic Egypt. Tomb biographies also exist for nobles and some commoners throughout the rest of ancient Egyptian history. Lichtheim notes that, from the First Intermediate Period on, for many individuals, a shortened biography would be relegated to the tomb stela which also contained an offering prayer and an offering scene, making the stela a “self-contained memorial” (Breasted, 1906; Lichtheim, 1975: 8, pp. 15–28).

A second literary genre, Instructions Literature, is among the Old Kingdom’s greatest contributions to Egyptian writing. This category is also known as Wisdom Literature, which Miriam Lichtheim calls the “second major literary genre created in the Old Kingdom” (Lichtheim, 1975, p. 5). They are written in the guise of the advice of a King, Prince or Vizier to his son. The earliest known example is the *Instructions of Hardjedef*. The sage Hardjedef (Hordjedef) was the son of Kheops (Khufu) in Dynasty 4. He also figures as a participant in the *Three Tales of Wonder* (from the Papyrus Westcar in the Egyptian Museum of Berlin). Prince Hardjedef claims to have written the instructions for his son, Au-ib-re. Not too much of his Instruction has survived, but his name is always listed among those of

Writing in Egypt in Its Literary Context,

Used with his permission)

the great sages of Egypt (Simpson, 1973, pp. 340–341). Lichtheim (1975, pp. 5–7 and 58–59) considers all three of the earliest Instructions (Hadjedef, Dynasty 5, and Kagemni and Ptahhotep, late Dynasty 6) to be pseudepigraphical (Pseudepigrapha (from the Greek words *pseudos* = false and *epigrapho* = write) describes texts whose claimed authorship is unfounded in actuality. The authenticity or value of the work itself, which is a separate question for experienced readers, often becomes sentimentally entangled in association. Yet few Hebrew scholars would insist that the Song of Solomon was written by the King of Israel, or ascribe the Book of Enoch to the prophet Enoch) works.

Another well-known example of this genre is the *Instructions of Ptahhotep*. The sage Ptahhotep, who, supposedly, was the vizier of the Fifth Dynasty pharaoh Izezi (2388–2356 BCE), provides maxims of good and polite conduct and of good speech.

These works constitute a form of political propaganda in a literary format. They posit that order and *ma'at* (justice and balance) are only possible when there is a strong and benevolent monarch on the throne of a united Egypt. In addition, they offer advice on proper behavior that reflects the mores of nobles of Dynasty 5 and Dynasty 6.

A third example, *The Instruction to Kagemni*, most likely written during Dynasty 6, alleges to be the advice given to Kagemni, the vizier of Huni, the last king of Dynasty 3 and of Snefru, the founder of Dynasty 4. The beginning of Kagemni's Instruction is lost, and its true date and authorship are unknown.

The Instruction of Merikare was supposedly written by King Khety II (ca. 2100 BCE), the father of Merikare of Dynasty 10. His (Merikare's) capital was at Herakleopolis. However, most scholars believe that it was actually written by scribes at the court of Merikare. Its uniqueness lies in its new dimension as a royal inscription in which a dying king bequeaths the throne to his son and successor and offers him advice on how to be a good king (Lichtheim, 1975, pp. 9–10).

The Instruction of Amenemhet I (or Amenemes I), supposedly written by Amenemhet I to his son Sesostris I (Senwosret I), of the Middle Kingdom (Dynasty 12), is a more famous example of this genre. The serenity and balance in Egyptian society as it appeared during the Old Kingdom had been replaced by the political and economic turmoil and social upheaval of the First Intermediate Period. Even though order had been restored by the Kings of the Middle Kingdom, our literary evidence suggests that the crown represented a heavier burden for the monarchs of the Middle Kingdom, and that the dangers of civil strife and revolution were lurking just below the surface. The apparent assassination of Amenemhet I (alluded to in both the *Instruction*

Writing in Egypt in Its Literary Context,

Fig. 10 Mereruka Wall Scene. The diminutive figure of Meri-Teti, son of Mereruka, is seen at the feet of the Vizier Mereruka. Mastaba of Mereruka (Dynasty 5) at Saqqarah (Photo by Brian Anderson. Used with his kind permission)

of *Amenemhet I* and *The Story of Sinuhe*) suggests that things had gone awry and that men were doing evil things. In the *Instruction of Amenemhet*, the dead King (Amenemhet I) appears as a ghost to his son Sesostri I - (or Senwosret I), tells of his assassination in the palace at the hands of his own palace guard, and suggests that it was instigated by someone in the harem. He advises his son to rule with a strong hand and to trust no one in the “day of evil” (Erman, 1927, pp. 72–74; Lichtheim, 1975, pp. 135–139; Parkinson, 1997, pp. 203–211; Pritchard, 1955, pp. 418–419; Simpson, 1973, pp. 193–197).

The Teaching of Duaf’s Son Khety, elsewhere known as the “Satire of the Trades,” also dates to the Middle Kingdom and proclaims that the most exalted profession is that of the scribe. The writer belittles all other occupations by listing all the hardships experienced by those employed in them (Parkinson, 1991, pp. 72–76).

The Prophecies of Neferti (Erman, 1927, pp. 110–115; James, 1979, p. 102; Lichtheim, 1975, pp. 8–9 and pp. 139–145; Pritchard, 1955, pp. 444–446; Simpson, 1973, pp. 234–240), the *Admonitions of Ipuwer*, and the *Prophecy of Nefer-rohu* represent a new departure in Egyptian literature. Neferti was a lector priest (literally, “he who carries the ritual”) at Bubastis during

the reign of Amenemhet I. This composition purports to be the prophetic vision of someone at the court of Snefru of Dynasty 4 who predicted the coming of the troubles of the First Intermediate Period and of Egypt’s savior, Amenemhet I, the first king of Dynasty 12. In other words, this piece was probably written to justify the seizure of the throne of Egypt by Amenemhet I. Neferti and Ipuwer address the problem of evil and proclaim that a strong monarchy is the only way to protect Egypt from its dangers. The pronouncements of the sage Ipuwer are reminiscent of those of the Biblical Prophets who chastised the Kings of Israel for not doing their religious and political duties.

The Admonitions of Ipuwer was probably written in the early years of Dynasty 12 and is generally interpreted as being either a warning to a king about the disastrous consequences of misrule or else as a means of contrasting the faithfulness of a good king (presumably one of the Dynasty 12 rulers) with the inadequacies of a bad king whose failure to tend to the religious and political duties of the throne resulted in the chaos and anarchy of the First Intermediate Period.

Nefer-rohu foresees the coming of Amenemhet I and speaks of him in such familiar terms that scholars are convinced that his prophecy was actually written during the reign

Writing in Egypt in Its Literary Context, Fig. 11 Deir el-Bahri Offerings. In the private tombs of the nobles of the Old Kingdom, the List of Offerings consisted of prayers and items meant to provide sustenance to the decedent in the afterlife. In a similar manner, the royal temples of the New Kingdom, Kings portrayed themselves making offerings to the gods (see Fig. 6). Here we see a wall relief from Hatshepsut's funerary temple that depicts her offerings to the god Amun (Photo by William S. Arnett. Used with his permission)

of Amenemhet (Erman, 1927, pp. 110–115; Pritchard, 1955, pp. 444–446).

The Song of the Harper dates to the First Intermediate Period, the era of disunity and civil and social unrest following the collapse of the Old Kingdom. It reiterates the above-mentioned concern for the loss of order and expresses the sense of futility in providing and protecting the “houses of eternity” (tombs) of the kings and nobility. In addition, the song offers an unprecedented philosophy of pessimism and skepticism concerning the shortness of life and the uncertainties of life after death (Erman, 1927, pp. 14–29; James, 1979, p. 98; Lichtheim, 1975,

Writing in Egypt in Its Literary Context, Fig. 12 The female Pharaoh Hatshepsut presents offerings to the God Amun. Funerary Temple of Hatshepsut at Deir el-Bahri (Photo by William S. Arnett. Used with his permission)

pp. 193–197, 222–235; Parkinson, 1991, pp. 36–37; Pritchard, 1955, pp. 18–22; Simpson, 1973, pp. 57–74). Was this pessimism truly reflective of a new Dawn of Conscience, as Breasted suggested (1976), or was it simply an irreverent farce from some popular poem or drinking song?

The Middle Kingdom (considered by later generations of Egyptians to have been the golden age of Egyptian culture and history for its art, calligraphy and literature) also produced a popular piece of prose, known as the *Story of Sinuhe*, a work of historical fiction. It depicts the adventures of an Egyptian nobleman who fled into exile in Palestine, perhaps because he feared he would be implicated in the murder of King

Amenemhet I, and only returns near the end of his life to be buried in his homeland. The story also presents Senwosret I (Sesostris) as a benevolent king who restores *ma'at* (truth, the world order,

justice, etc.) and welcomes Sinuhe back to Egypt with open arms. It provides the earliest literary description of Palestine and portrays it in Bible-like fashion as a land of milk and honey:

“Abundant was its honey, many sweets were made for me, and milk dishes of all kinds.”

Scholars are fairly certain that they know the identity of the author of this famous story. His name was Achthoes. *The Papyrus Chester Beatty IV*, in the British Museum (#10684) avers that, “It was he who made a book as the Instruction of

King Sehetepibre.” The latter is the name taken by Amenemhet I when he assumed the throne. Achthoes is also known to have written the previously mentioned Instruction book entitled the *Satire of the Trades* (Erman, 1927, pp. 14–29; James, 1979, p. 98; Lichtheim, 1975, pp. 222–235; Parkinson, 1997, pp. 21–53;

Pritchard, 1955, pp. 18–22; Simpson, 1973, pp. 57–74).

The Tale of the Eloquent Peasant, like so many of our surviving Egyptian literary texts, is also a product of the Middle Kingdom. In fact all of the manuscripts containing this story come from that era. It may be the mere chance of discovery, but it could also mean that, unlike other tales from the twelfth Dynasty, this particular example did not enjoy continued popularity during the later New Kingdom. Social equity and the right of commoners to expect fair treatment at the hands of the nobility and the government are the central themes along with the unexpected eloquence of a peasant (Erman, 1927, pp. 116–131; Lichtheim, 1975, pp. 169–184; Parkinson, 1991, pp. 64–65; Pritchard, 1955, pp. 407–410; Simpson, 1973, pp. 31–49).

The Tale of the Two Brothers, a work composed in Dynasty 19 (ca. 1210 BCE), has elements similar to the story of Joseph and the wife of Potiphar in Genesis 39. But, as the noted Coptic scholar Plumley pointed out in 1958, the two stories have some common aspects, “but it would require much greater similarity of detail between the Egyptian and the Hebrew stories to justify the oft-made suggestion that the Egyptian story is the origin of the incident described in Genesis.”

The Capture of Joppa, found with the *Story of the Doomed Prince* on the same papyrus (Harris, #10060, Br. Museum), is an historical romance dealing with General Djehuty, who served

Thutmose III in his campaigns in Syria-Palestine (ca. 1504–1450 BCE) and depicts an event otherwise unknown in the official Egyptian annals. Djehuty outwits the city's defenders by having him and several Egyptian soldiers smuggled into Joppa in baskets (Erman, 1927, pp. 167–169; James, 1979, p. 112; Pritchard, 1955, pp. 22–23; Simpson, 1973, pp. 81–84) (Fig. 18).

Space permits only the briefest listing of several other categories of Egyptian writing that have survived in great quantities on papyri and ostraca, as well as in the form of inscriptions and paintings on the walls of tombs and temples. The reader interested in further study will find more scholarly information and examples of texts in the linked sites. These additional genres of Egyptian literature include both secular and religious songs. In addition to the above-mentioned Harper's Songs, Egyptian love songs, dating to the New Kingdom, have also survived. These have a timeless quality and can be very romantic and erotic (Foster, 1974; Simpson, 1973, pp. 296–326).

Egyptian Poetry is found in several forms, including: hymns to the gods and king; love poetry that is both beautiful and passionate, and the above-mentioned Songs of the Harper, filled with uncharacteristic pessimism and practical questioning of time-honored beliefs. Some of this poetry has been compared to the Biblical Song of Songs. It has also been noted that Egyptian love lyrics “are part of the same ancient tradition of erotic verse which we find in the cultures of the Fertile Crescent” (Erman, 1927,

Writing in Egypt in Its Literary Context, Fig. 18 Golden Bowl of Djehuty. A solid gold bowl from the tomb of the General Djehuty. He served the Pharaoh Tuthmosis III. His tomb was found at Saqqara in 1824 but the contents were distributed and the site of the tomb is now lost. Louvre Museum (Photo by Jon Bodsworth. Used with his kind permission)

pp. lviii–lxii; Erman, 1966, pp. xxxi–xxxviii; Kaster, 1968, pp. 220–233; Lichtheim, 1975, pp. 11–12; Simpson, 1972, pp. 169–326) (Figs. 19 and 20).

Egyptian hymns are not only dedicated to the gods of Egypt, but also to the kings. The most famous Egyptian hymn is the Hymn to the Aton (Aten), which, allegedly, inspired the wording in Psalm 104 in the Hebrew Bible. It is the earliest known monotheistic text in history (Pritchard, 1955, pp. 370–371; Simpson, 1972, pp. 289–295).

Egyptian letters have survived on papyrus dating as early as the Sixth Dynasty (ca. 2250 BCE). Many of the surviving letters were used as models in the education of scribes who were trained to master the style necessary for official, business, and interpersonal communication.

Egyptian Religious Texts constitute by far the greatest number of written Egyptian texts that have survived. The most common examples of this genre include the famous Pyramid Texts, the Coffin Texts, The Book of the Dead, Myths and Creation stories, Oracles and Prophecies, Hymns and Prayers, etc.

Writing in Egypt in Its Literary Context, Fig. 19 Egyptian Harp. One of several Egyptian musical instruments found in Egyptian tombs. New Kingdom period (British Museum) (Photo by Jon Bodsworth. Used with his kind permission)

The most famous of the Egyptian Mathematical Papyri and texts is the *Rhind Mathematical Papyrus* (ca.1580 BCE). It is believed to have been composed by a scribe named Ahmose during the reign of King Ahmose Auserre in the Hyksos era. It is in the British Museum.

Egyptian Medical papyri and texts are fairly plentiful. The British Museum alone has eight examples. Three of the more important ones include *The London Medical Papyrus* (#10059) which dates to the eighteenth Dynasty, *The Chester Beatty Medical Papyrus VI* (#10686) and *Chester Beatty X* (a nineteenth Dynasty text dealing with aphrodisiacs). Perhaps the most famous medical text is the *Edwin Smith Surgical Papyrus*, which is housed in the New York Academy of Medicine. Breasted published a folio-sized edition on this papyrus in 1932. It is a remarkable, scientific approach to the practice of medicine that deals with 48 different kinds of injury cases and covers surgical treatments for the head and thorax. Ancient Egyptians even knew that a mother's urine is the secret to the determination of the sex of an unborn baby. One of the remedies that it recommended for the treatment of facial wrinkles was described as a lotion that had "proved effective myriads of times." Another very important medical text, the *Ebers Medical*

Writing in Egypt in Its Literary Context,

Fig. 21 *Amduat* scene from the Tomb of Pharaoh Ay. West Valley of the Kings (WV 23). The 12 baboons represent the 12 h of the night (Photo by Brian Anderson. Used with his kind permission)

Papyrus (in Leipzig) offers some insights into Egyptian surgical techniques. There is a section on the heart and its vessels, and one of its remedies calls for the use of castor oil as a laxative.

The Egyptian concern with the stars and planets led to serious study of astronomy. From the alignment of the pyramids with the stars to the many myths associated with the day and night-time journeys of the sun, they have left us both physical and textual evidence documenting their obsession with the universe in which they lived. The earliest evidence of Egyptian astronomical observation takes the form of a series of texts in

the lids of coffins dating to the Ninth Dynasty (ca. 2150 BCE) (James, 1979, pp. 124–126).

In the New Kingdom, many of the royal tombs in the Valley of the Kings were decorated with scenes from the *Amduat* (“that which is in the netherworld”) (Figs. 21 and 22).

These are found in the form of the *Book of the Day* and the *Book of the Night* in a burial chamber in the tomb of Ramses VI (1144–1136 BCE). These books deal with the day and night journeys of the sun god Ra – in the night, as he travels through the body of his mother, Nut, the goddess of the heavens, and in the day, as he travels across

Writing in Egypt in Its Literary Context,

Writing in Egypt in Its Literary Context, Fig. 23 The Goddess Nut and the Book of Gates. This painted scene (from the ceiling of the tomb of Ramses VI (KV 9) in the Valley of the Kings, ca. 1141–1133 BCE) shows the upper half of the goddess Nut as she prepares to swallow her

“son,” the sun god Ra, at the end of his daily journey across the sky. The ceiling paintings portray astronomical themes as well as the various stages of the night journey of the sun god through the underworld (Photo by Brian Anderson. Used with his kind permission)

her body, after she gives birth to him once again in the endless cycle of birth, death and regeneration (Allen, 1988, pp. 38–49; Hornung, 1992, pp. 95–113; Shaw & Nicholson, 1995, pp. 29, 62, 79, 106, 273, 290, and 299; Silliotti, 1997, pp. 64–6) (Figs. 23 and 24).

Examples of Egyptian writing have survived in fairly great quantities but there are

considerable lacunae in our textual knowledge. These lacunae are the result of damage to portions of extant texts as well as to the destruction of tremendous quantities of texts recorded on perishable materials which did not survive the ravages of nature and time. We are indebted to the Egyptians for their strong desire to record their history, religious and philosophical beliefs,

Writing in Egypt in Its Literary Context,

Fig. 24 The Goddess Nut and the Book of Gates (b). This scene is a continuation of the previous figure and shows the lower half of Nut's body where she gives birth to Ra at the beginning of each new day. The Book of Gates illustrates the Egyptian interest in astronomy and the universe as well as a new departure in their obsession with the afterlife and the underworld (Photo by Brian Anderson. Used with his kind permission)

as well as the fruits of their imagination and scientific, astronomical, medical, mathematical, and biological inquiries. When considering the great intellectual and cultural debt that the modern world owes to this Egyptian legacy, we can only regret that we have thus far been unable to attain the even greater quantities of writings that remain outside of our reach and understanding.

Writing in India

This entry deals first with the evolution of writing in India in chronological order, then with the uses of writing.

Indus Civilization (c.2600–1900 BCE): A Forgotten Logosyllabic Script

The Indus or Harappan Civilization flourished in and around the Indus River in present-day Pakistan and western India c. 2600–1900 BCE. The most extensive urban culture of its time, it had its own script, which perished without descendants

when the Indus cities and their urban life-style collapsed. Thousands of short inscriptions have been preserved, mostly seal stamps and their impressions (Fig. 1). Because the Indus script has no obvious affinity with any other script (a debated issue) and because there are no multilingual texts, it is exceedingly difficult to decipher.

Indus merchants sailed to the Gulf and Mesopotamia, where about 40 seal stamps with Indus script have been found. Like the Mesopotamian seal cylinders, they were used to seal containers of goods to prevent unauthorized opening. The Mesopotamian seal inscriptions contain names and titles of the seal owners, and so do probably the Indus seal inscriptions. It is also likely that the Indus script functioned like the Mesopotamian cuneiform script.

Cuneiform writing started as the world's oldest script, Archaic Sumerian (c. 3300–2900 BCE). Initially pictographic, its signs depicted human beings and animals and their body parts, plants and other things. Written on clay with wedge-shaped lines, however, the original shapes became unrecognizable, but the cuneiform script remained a logosyllabic writing system. Each sign either denoted the depicted word (logos in Greek)—an arrow-shaped sign Sumerian *ti* “arrow”—or “syllabically” its sound irrespective of its meaning —the arrow-shaped sign could also stand for Sumerian *ti* “life” or *ti* “rib.”

When the Indus script was created c. 2600 BCE, all the existing scripts were of the logosyllabic type. The Egyptian hieroglyphs and the proto-Elamite script (used widely in the Iranian plateau) were both inspired by the Archaic Sumerian script in the late fourth millennium BCE. The Indus people probably got the idea of writing from the proto-Elamites, but used their own traditional symbols and invented new ones while devising their own script.

In 2004 it was asserted that the Indus script is no real writing system reproducing speech, but only a collection of non-linguistic symbols. However, it radically differs from such symbols widely used in and around the Indus Valley for centuries right until the Indus script came into being. These earlier symbols, called

Writing in India,

The impression (in mirror image) was read from right to left (Photo Erja Lahdenperä for the University of Helsinki, courtesy Archaeological Survey of India)

“potter’s marks” because they are mainly found on ceramic vessels, usually occur one by one, whereas the signs of the Indus script occur in long and regular rows, with repeated sign sequences. The script emerged when the weights and measures were standardized and the society became more stratified and completed large and complex building projects.

The Indus script has been “deciphered” more than a hundred times. Most attempts assume the underlying language to be Indo-Aryan, which however was hardly spoken in South Asia before 2000 BCE. The horse is a very important animal in the Rigveda, the oldest surviving Indo-Aryan text composed by 1000 BCE, but the horse is not found among the many animals represented in the Indus art. On the other hand, the Rigveda contains some Dravidian loanwords. Dravidian languages such as Tamil are now mainly spoken in South India, but one (Brahui) survives in Baluchistan and the Indus Valley. Systematic and cross-checked interpretations for more than 20 signs (out of c. 400) based on the Dravidian hypothesis have been presented and won some recognition, but generally speaking the Indus script is still considered undeciphered.

Vedic Times (c. 1300–500 BCE): Accurately Memorized Oral Literature

After the collapse of the Indus Civilization c.1900 BCE its script was forgotten. The Indo-Aryan speakers, who came to South Asia from the northwest during the second millennium BCE, were illiterate, but created sophisticated oral poetry. Over thousand hymns were assembled into a collection called Rigveda c. 1000 BCE. Elaborate repetition techniques developed to assist its accurate memorization have safeguarded the Rigveda from the hazards of oral transmission. Learning the Rigveda by heart takes 5 years of hard work in early youth, and keeping it in mind requires daily repetition. This way of memorizing Vedic texts still goes on, and their human repositories often are more reliable than manuscripts. The rules created for the preservation of oral literature have been scrupulously observed, and their further development led to astonishing achievements in the study of phonetics and grammar without the aid of writing in the first millennium BCE.

As their standard beginning (“Thus have I heard ...”) indicates, the earliest Buddhist texts of the fourth and third centuries BCE were likewise orally transmitted.

Old Persian Rule (c. 500–326 BCE): Writing Re-introduced: Aramaic and Kharoṣṭhī

Around 518 BCE, Darius the Great conquered the northern and southern parts of the Indus Valley: they were attached to the Persian Empire as the provinces of Gandhāra and Hinduś for the next two centuries – until Alexander the Great took them over and soon thereafter died in 323 BCE. The Persian bureaucracy used the *Aramaic script* all over the Empire, from Egypt to India.

Aramaic is a variant of the Semitic consonantal alphabet which had been created in ancient Syria much earlier (c. 1600 BCE) on the basis of the uniconsonantal signs of the Egyptian script (where signs could express words that contained one, two or three consonants). Semitic and Hamitic (i.e., Egyptian) languages can be understood even if the vowels are left unwritten, as they usually are, but the consonantal alphabet is not so suitable for writing other languages.

The Aramaic script was adjusted for writing Indo-Aryan languages by adding markings that express vowels to the consonantal signs; if such an additional sign was missing, the respective consonant was understood to be followed by the most frequently occurring short vowel *a*; consonant groups were expressed by combining consonant signs together. Signs for consonants not represented in the Aramaic script were also created. Why this new syllabic alphabet is called *Kharoṣṭhī* is a much debated question. Kharoṣṭhī

greatly resembles the Aramaic script, also in being written from right to left. It was used in the northwest of the Indian subcontinent until c. 200 CE, and in Central Asia until c. 600 CE (Fig. 2).

From the Mauryas to the Guptas (c. 320 BCE–550 CE): The Brāhmī Script

After Alexander's death, the Persian provinces Gandhāra and Hinduś were quickly incorporated in his emergent empire by Candragupta, the founder of the Maurya dynasty (c. 325–183 BCE). Candragupta's grandson Aśoka (in power c. 268–232 BCE) is one of the most famous rulers of India. Aśoka's rock and pillar edicts, distributed all over his large empire, are the earliest directly preserved historical records of ancient India. Written in local dialects they also provide precious information about the prevailing linguistic situation. Aśoka's inscriptions were written in the Kharoṣṭhī script, in the *Greek script* (introduced by Alexander and used by the succeeding Indo-Greeks in the Indo-Iranian borderlands) and in the *brāhmī script*, which is the basis of most writing systems used in South Asia in later times. The Indian tradition considers brāhmī as an invention of the creator god Brahṁā, who is depicted as holding a palm leaf book in the hand.

The brāhmī script is a syllabic alphabet functioning like the Kharoṣṭhī, but with its distinction of short and long vowels and different initial vowels still more perfectly adjusted to

Indo-Aryan languages, and written from left to right. It may have been commissioned by Aśoka for his rock edicts around 260 BCE; some improvements in the script appear in the pillar edicts about two decades later (Fig. 3). In that case the brāhmī script is based on the Kharoṣṭhī and Greek scripts. This recent conception about the origin of the brāhmī is however contradicted by the likewise recent discovery of potsherds inscribed with brāhmī characters in stratum J (c. 450–350 BCE) at Anurādhapura in Sri Lanka. If the dating is correct, these finds support the traditional derivation of the brāhmī script from the Phoenician consonantal alphabet long before Aśoka. Alexander’s admiral Nearchus speaks of Indians sending each other letters written on cotton cloth, but this statement limited to the northwest may refer to Persian administration in Aramaic. According to other Greek authorities quoted by Strabon, the Indians did not use writing. The Greek ambassador Megasthenes stationed in the Mauryan capital c. 300 BCE specifies that the Indians had only unwritten laws.

Post-Classical Period (550 CE Onwards): Diversified Scripts

Almost all the writing systems that are nowadays being used to write South Asian languages go back to the brāhmī script, which remained in use until the collapse of the Gupta Empire c. 550 CE. The late variety of brāhmī used in North India was c. 600 CE transformed into two principal types of script.

The *siddham* or *siddhamāṭṭṛkā* script (Fig. 4) was in general use in North India until c. 1000 CE, and the *Bengali* (Fig. 5) and *Tibetan scripts* and the *śāradā* script of Kashmir are derived from it. The siddham script spread also to Central and East Asia, being still used to write Sanskrit magical formulae in Japan.

The *nāgarī* (later called *devanāgarī*) script has been used to write especially Sanskrit (Fig. 6), Hindi, Marathi and more recently Nepalese. The *gurumukhī* script of the Punjabi language and the *Gujarati script* also go back to early variants of the nāgarī script. The southern

Writing in India, Fig. 7 Tamil script in an edition of the Old Tamil classic Tirukkura (aphorism 93): “Virtue consists in speaking sweet but truthful words with a smiling face and a friendly look”

Vijayanagara empire (1336–1565) used the *nandināgarī script* imported from Maharashtra.

Tamil was written in the *brāhmī script* from the second century BCE. This South Indian variant of *brāhmī* is the basis of the relatively simple *Tamil script* used today (Fig. 7), as well as of the much more complex *grantha script* used in Tamil Nadu for writing Sanskrit, which in turn is the basis of the *Malayāam script* used in Kerala.

Kannada and *Telugu*, the two further literary members of the Dravidian language family in South India, are written in closely related script derived from the Cālukya kingdom. The Sinhala language of Sri Lanka is written in the *Sinhala script* that has evolved from the Sri Lankan variant of *brāhmī*.

The *Arabic script* imported to South Asia from Persia by the Muslims since the eighth century

CE has been used to write especially Persian – the court language of the Moghuls – and (with important modifications) Urdu – the Muslim variant of Hindi – and Kashmiri, and various minor Indo-Aryan and Iranian languages spoken in Pakistan. The *Roman alphabet* was brought to South Asia by the European colonialists who came to stay with the Portuguese in 1498, and which is used for writing not only European languages but also Konkani spoken around Goa.

Uses of Writing

Inscriptions and Coins

Because they usually can be exactly located and also dated, inscriptions engraved in stone are very important sources of political and cultural history in India. There is a continuous inscriptional tradition ever since Aśoka's edicts (from c. 258 BCE), but their number increases substantially only c. 700 CE. From c. 300 CE, royal grants of villages and the like were engraved on sealed copper tablets. Altogether c. 100,000 inscriptions in stone or metal are known today. Thousands of inscriptions in Indian languages and scripts have been discovered also outside South Asia, in Egypt, Afghanistan, Central Asia, China and most parts of South East Asia.

Numismatic material plays a crucial role also in the history of the dynasties of Iranian origin in the centuries around the beginning of the Christian era. The Indo-Greek kings are known almost exclusively from their coins. Being bilingual, these coins moreover opened up the ancient history of India. The text written in the Greek script and language on the obverse side is rendered in the Prakrit language written in the Kharoṣṭhī script on the reverse side. James Prinsep in the 1830s worked out how to read Kharoṣṭhī and applied the results to the Kharoṣṭhī inscriptions of Aśoka. These readings in turn opened up the secrets of the forgotten brāhmī script.

Manuscripts

The book in ancient India was usually written on long leaves of the wine palm (*Borassus*

flabelliformis), which had first been cut into regular rectangular form. Wooden covers of the same size were usually put on both sides of the bundle to protect the leaves from breaking. The ready bunch of leaves and covers was then pierced in one or two or three places in the middle, so that a rope could be inserted through the leaves to bind them together into a bundle. The long binding rope had some stopper at both ends which prevented it from coming out when the book was opened and the rope loosened: the reader places the bundle on the ground, and then turns the leaves over from one pile to another. When the book is closed, the leaves are collected together, the rope is tightened, and its long loose end is wound many times around the bundle. "Binding" the leaves thus together has given the ancient Indian book one of its Sanskrit names, *grantha*.

While writing on the empty leaves the scribe would leave some margin around the edges and the cord-holes. This was a precaution to secure that no text would be lost if the leaf was broken at its edges. The leaves would also be numbered, by putting a running number in the right or left margin of the obverse or reverse side. The margins could also be used for inserting in them corrections (for letters marked in the text with symbols of cancellation or painted over), supplementary texts (parts of text accidentally omitted in copying but noted afterwards), glosses (explanations of difficult words or expressions) or subtitles (indicating the contents of the text at that place) (Fig. 8).

The colophon at the end of the manuscript often contains not only the name of the work and its author but also the name of the scribe and possibly his genealogy and domicile and the date of completing the manuscript. Just as the author of a literary work, the scribe also starts with an auspicious word and a prayer, most frequently an obeisance to Gaṇeśa, the elephant-headed god of success, who is expected to see the task to its conclusion and to remove any obstacles. Gaṇeśa is thought to have written down the great epic Mahābhārata at the dictation of its compiler Sage Vyāsa: as the divine scribe he broke one of his tusks and used it as a stylus.

Writing in India, Fig. 8 Verso side of leaf 12 of a paper manuscript written in the devanāgarī script, dating from the seventeenth century. The manuscript contains the Āraṇyaka Gāna of Sāmaveda. Sāmavedic songs composed

c. 1000 BCE are the world's oldest known music. The small numeral signs over the lines of text are musical notation. Textual divisions are highlighted with red colour (Photo Asko Parpola)

This agrees with the South Indian practice of scratching signs on the surface of the leaf by means of a sharp iron stylus. The incised lines were afterwards made more visible by means of the juice of plants rubbed over the leaves. In North India, the scribe would use ink (made of soot) and either a brush or a pen made of reed (Fig. 8). The same methods were used if the manuscript was illustrated with miniature pictures – painted in several colours in North India, incised in South India (from Orissa to Tamil Nadu and Kerala).

In northwest India, parchment may have been used for writing during the Iranian rule, since Sanskrit *pustaka* “manuscript” or “book” is an Iranian loanword denoting “book” and “hide, parchment, bark” in the donor language. Birch bark was used as writing material in Kashmir. Paper started being used in North India around 1,000 years ago, but in South India much later. Paper used to be cut in long rectangular leaves which imitate the shape of the traditional writing material, the palm leaves (Fig. 8). The same applies to thin wooden plates that have likewise been used as writing material, especially in Sri Lanka and in communities of Indian origin in South-East Asia.

Normally manuscripts did not survive long on account of the climate and insects, even if they were treated with vegetable oils or kept in smoky

places avoided by insects. Palm leaves usually last maximally some 3 or 400 years. In exceptional circumstances palm leaves have survived much longer, however: the oldest manuscripts are from the first centuries CE and come from the dry climate of Central Asia. There they have been kept in pottery vessels – exciting discoveries of Buddhist birch bark and palm leaf manuscripts have been made in recent years in Afghanistan and northern Pakistan. Reed baskets (*piṭaka*) have provided another and more usual implement for storing manuscripts: at one time the entire Buddhist canon could be put into three baskets. In ancient India, temples, monasteries, royal palaces and even private persons had manuscript libraries, which could contain even tens of thousands of volumes. Today millions of Indian palm leaf or paper manuscripts survive in public and private libraries in and outside South Asia.

On account of their poor durability, texts to be preserved in writing had to be copied over and over again, which led to accumulating mistakes. Such copying mistakes have distorted literary texts, but if a number of manuscripts are available, their comparison may enable reconstructing a genealogy of copying and reconstituting the original text.

Palm leaves have been used in South India until the early twentieth century not only for writing literature, but also for book keeping and

for legal documents, with seal impressions attached. On the other hand, literature – especially voluminous Vedic texts – has been handed down also in a millennial oral tradition until the present day.

Writing in Japan

Christopher Seeley

The modern Japanese writing system employs predominantly a combination of Chinese characters (1445 are taught in school education) and syllabic signs called *kana* (close to 100 in total, in two sets, viz. the angular *katakana* and the more rounded *hiragana*) (Henshall, Seeley, & de Groot, 2003). These are used together with an admixture of other signs such as Arabic numerals and Roman letters. The following sentence is an example of how the different elements function together:

Otōto wa sugoi esu-eru mania de, jūnigatsu ni mata Suisu e iku koto ni natte imasu. 'My younger brother is a huge fan of steam locomotives, and it has been arranged for him to go to Switzerland again in December.' Chinese characters are used for the noun *otōto* 'younger brother', the suffix *-gatsu* 'month (of the year)' and the first part of the stem of the verb *iku* 'to go'. *Hiragana* are employed for elements which include particles such as *wa* (topic indicator), *e* 'to, towards', for the adjective *sugoi* 'great; awful' and the second syllable of *iku* and also for the post-verbal

construction *koto ni natte imasu* ‘it has been arranged to —’. *Katakana* represent two European loanword items (*mania* ‘fan, enthusiast’ and *Suisu* ‘Switzerland’), while an acronym-type European loan (*esu-eru*) is represented by upper case Roman letters. Arabic numerals are used here to represent *jūni* ‘twelve’ in *jūnigatsu* ‘December’, which can otherwise be written all in characters, viz. 十二月 (id.).

Although still very complicated, the system in use today represents a substantial simplification of that which was employed in the early part of the twentieth century. It reflects a heritage of cultural and linguistic history in Japan that extends back to early in the first millennium A.D.

Around 400 A.D. the Japanese, who at that time had no writing of their own, actively adopted Chinese writing. At this very early period, it was the Chinese language, not Japanese, which was represented directly in written form. Due to the difficulties associated with using what for the Japanese was a foreign language, together with a very large and complicated character set, initially there was heavy reliance on Chinese and Korean scribes (Seeley, 2000, pp. 3–15).

As time went by, the Chinese script was adapted to represent the Japanese language, sometimes directly, but often in a convoluted manner. The *Kojiki* (*Record of Ancient Matters*) of 712, notable as the earliest large-scale compilation to have survived to the present, constitutes a useful example of such adaptation. The *Kojiki* preface is in Chinese, which was appropriate as the most formal style in a document addressed to the sovereign; the main part of the text is in a hybrid form which reflects Japanese influenced by Chinese (selected by the compiler with the stated aim of ease of reading [!]). The Japanese songs interspersed in the text are represented by Chinese characters employed for their sound value so as to minimise the ambiguity of reading in material of an oral nature (Seeley, 2000, pp. 40–46). At an early period, the Japanese had the means to represent their own language directly in writing, but the overwhelming prestige of Chinese culture meant that more often than not they chose a Chinese-orientated style.

Despite the high standing of written Chinese in Japan (and Japanese attempts at

Chinese composition), direct representation of Japanese also had its place, and this more straightforward form of writing enjoyed a substantial rise in popularity from around 900 A.D. This was due to a development early in the ninth century in the context of Buddhist works in Chinese. Abbreviated Chinese characters employed for their sound value as phonograms – the forerunners of modern *katakana* (used today for such purposes as representing loanwords of mainly European origin) and *hiragana* came to be used quite extensively as a convenient means of annotating the text, albeit sometimes only minimally and sporadically, to help read or ‘decode’ it as Japanese. Abbreviation was achieved through a process of (1) writing rapidly (cursively) and thereby omitting strokes (e.g., 女 > め *me*, 弟はすごい S L マニアで、12月にまたスイス波 > は *ha*) or (2) isolating one part of a character phonogram and taking it to represent the whole (e.g. 保 > 呆 *ho*, 加 > カ *ka*). After a time, *katakana*-type signs tended to be favoured for utilitarian purposes such as annotation, while *hiragana*-type signs came to be used extensively for Japanese poetry and prose. Women were seldom given the opportunity to acquire grounding in Chinese characters, and the convention arose whereby writing in phonograms of the cursivised variety tended to be associated with women. This is reflected in the early term for *hiragana*-type signs, *onna-de*, and ‘women’s hand/script’. This is best understood as meaning the script typically used by women rather than exclusively by them, for men certainly sometimes employed kana of this type (Seeley, 2000, pp. 59–89).

While some Japanese texts were written entirely in kana, much more commonly there was at least a small admixture of Chinese characters. In the early period, characters were sometimes employed as a convenient means of representing Chinese loan morphemes which involved sound segments difficult to represent in a still emergent system of kana signs. Orthography of this general type, which involved a combination of characters and kana, gradually assumed a position of increasing importance; the role played by Chinese characters as a guide

to disambiguating what would otherwise be a Japanese text consisting of a long string of kana signs spaced equidistantly should not be underestimated.

In spite of the above developments, broadly speaking, the cultural and linguistic importance of China continued to be very strong. Written Chinese, or rather an approximation of it, continued to be widely perceived as highly prestigious until modern times, is being used even at the beginning of the Meiji period (1868–1912) in some Japanese newspapers. Increasingly, though, the leaders of Japanese society were being influenced by the West. As a result of extensive debate on language and script, a movement evolved around the end of the nineteenth century with the aim of bringing written language more in line with spoken language (the *Genbun itchi* [Unification of Speech and Writing] movement) (Twine, 1991), and there was also support in some quarters for reducing the number of different Chinese characters in general use. In the year 1900 the Education Ministry (Monbushō) published a list of about 1,200 characters for use in primary school texts, together with a standardised set of kana signs and a partially simplified form of kana usage. However, there was still strong opposition from conservative elements to reform the writing system.

A radical turning point in the Japanese writing system occurred in the 1940s, following Japan's defeat in the Pacific War. In that very different environment, simplification of the written language and script was espoused as part of the movement to promote democracy. Changes effected included the adoption and promulgation in 1946 of a list of 1850 Chinese characters approved for active general use called the *Tōyō kanjihyō* (List of Interim Use Chinese Characters), followed by several supplementary lists aimed at restricting the number of readings associated with individual characters and increasing the number of officially approved simplified character shapes (e.g., 廣  へ行くことになっています。広, 藝  >芸). A more rigorous restriction took place in the area of given names which parents chose for newborn children: whereas previously it was

permitted to use any Chinese characters out of a potential corpus of tens of thousands, from late 1947 parents found themselves restricted by law in choosing from just the 1850 in the Interim Use List, or alternatively to use kana. This change was seen by many as excessive, and in 1951 this restriction was eased through a supplementary list of additional characters for use in names. 1970 onwards a significant relaxing of guidelines and regulations regarding the range of Chinese characters were used. The year 1981 saw the Interim Use List replaced by a modestly expanded new list (1945 characters) called the *Jōyō kanjihyō* (List of General Use Chinese Characters), which was given the status of a guide (*meyasu*) for usage, and the name character list has been repeatedly expanded, consisting now of close to 300 characters (Seeley, 2000, pp. 152–187).

In the Interim Use List era and before, advocates of script reform argued that kana or Romanisation should be adopted for Japanese because of the difficulties associated with mechanical production of text. A manual typewriter for Japanese was devised early in the twentieth century, but it required a specialist operator, and only about ten pages a day at most could be produced. The strength of the argument for script simplification was, however, compromised in the late 1970s with the development of a word-processor which featured Japanese language input in Romanisation or kana and output in conventional (character and kana) Japanese text. The mid 1980s then saw the appearance of portable and affordable machines which gave consumers the ability to handle Japanese text with output which encompassed the Chinese characters contained in a standard corpus of about 6,300 Chinese characters determined for universal data exchange by the Japan Industrial Standards Institute (Gottlieb, 2000; Seeley, 1994).

The popularisation of word processors and computers from the 1980s for Japanese has led to a significant rift between the number of characters taught in the school system and the corpus by more than three times the size accessible via computer-generated text. This discrepancy needs to be addressed and somehow accommodated.

Despite associated problems such as this, what seems certain is that the position of Chinese characters as a central feature of the Japanese writing system is assured for the foreseeable future.

Writing in the Middle East

Alan Millard

University of Liverpool, Liverpool, UK

Writing and the alphabet were two of the major inventions of the human mind. They were conceived and developed in the Middle East between about 3500 and 1000 BCE. Other writing systems appeared in China about 1200 BCE and in Central America during the first millennium BCE, probably independently, although the Chinese may have been indirectly influenced from Babylonia.

Cuneiform Writing

Writing began over 5,000 years ago in the developing urban culture of southern Mesopotamia known as the Uruk IV period. At first simple pictures were scratched on stone or clay tablets held in the hand. Some showed a complete object, such as a fish, and others part of an object, such as the head of a cow, while others cannot be identified. More than 1,200 signs were used in the

oldest known texts, which deal with the income and expenditure in kind of temples. The number of signs soon shrank to about 600, and as well as serving as word-sign (logograms), many also came to be used phonetically (phonograms) on the rebus principle. Thus in English the picture of a thin man beside a king read as ideograms could mean “The thin man is king” or “The king is a thin man,” but taking their values phonetically could yield the two syllables of “thinking,” a concept harder to express pictorially. The rebus principle enabled the script to express any words, including foreign terms and names. The syllabic signs are vowels (*a, e, i, u*), “open” (e.g., *ba, gi, du, am, ir, uz*) and “closed” (e.g., *bab, gim, dur*), and some longer ones (e.g., *alad, gibil*) (Fig. 1). Additionally, a small number of signs were placed before or after word signs to indicate their class. These determinative signs mark categories such as “man,” “woman,” “wooden object,” “fish,” “pot,” and plurality. By 3000 BCE the language of the texts is evidently Sumerian, a language unrelated to any other now known, and it is likely the script was invented by Sumerians. The Sumerian language appears to have many homophonous words, which suggests it may have been tonal, and so several signs can have the same phonetic value when transcribed into roman letters, which scholars distinguish by accents and subscript numbers (thus *sá* “to be equal,” *sa₄* “to name,” *sa₁₀* “to buy”). Simplification for speed and impressing a reed stylus on clay produced angular strokes and resulted in the signs rapidly losing their pictorial form, so becoming the wedge-shaped or cuneiform script. The range of texts expanded over the centuries from the accounts and lists of words by category of the earliest period to embrace almost every type of written composition. By ca. 2500 BCE archives of clay tablets include hymns and prayers, proverbs and wise advice, riddles, legends and myths, and brief historical records. At that time the script was adapted for writing the East Semitic Akkadian language (ancestral to Babylonian and Assyrian). Word signs could now be read in Akkadian, and a much wider use of phonetic values of signs became common as words were written syllabically (e.g., the word

sign “bull’s head,” read in Sumerian as *gud* and in Akkadian as *alpum*, could be written *al-pu-um*). While some texts were written almost wholly with syllabic signs, especially in the early second millennium BCE (the Old Babylonian period), scribes usually wrote with a mixture of syllabic and word signs, preceded or followed by the determinative signs. This system continued until the beginning of the Christian era, spread across the Near East, especially in the second millennium BCE, and was adopted for writing unrelated languages such as Elamite in Iran and Indo-European “Hittite” languages in Anatolia. The tens of thousands of clay tablets in modern museums attest the activity of scribes in writing down almost every aspect of life, but the script never lost its complexity, and so writing remained a specialized craft, usually the monopoly of the trained scribe.

Egyptian Writing

Egyptian hieroglyphic writing began almost simultaneously with the ancestor of the cuneiform script in Babylonia and was possibly influenced by it. (There are clear signs of other influences from Mesopotamia in Egyptian culture at the end of the fourth millennium BCE, e.g., the distinctive cylindrical seal.) The hieroglyphs are pictures and from the first were closely associated with narrative art, as is evident in predynastic carvings (e.g., the Narmer Palette) and thousands of later sculptures

and objects of all kinds. They were employed both as word signs (ideograms) and, through the rebus principle, as sound signs (phonograms). In the early stages over 1,000 signs occur, a number soon diminishing to 600 or 700 which were in regular use until Hellenistic and Roman times when the number multiplied enormously. In their day-to-day activities, clerks, writing rapidly on papyrus, reduced the hieroglyphic script to a cursive form, known as hieratic, examples occurring from the earliest dynasties onward. A highly cursive and abbreviated script, demotic, developed in the first millennium BCE and continued beside the hieroglyphs well into the Christian era. Both hieratic and demotic were written from right to left; the hieroglyphs could run in any direction. The hieroglyphs are, to modern eyes, purely consonantal; the ancient readers supplied the appropriate vowels, facilitated by the structure of the language, as in the West Semitic “alphabet” (see below). There are three classes of hieroglyphs giving phonetic, apart from their ideographic, values. The 26 with a single consonant are often called the Hieroglyphic Alphabet, but it is important to recognize that the Egyptians did not separate them from the other signs. Each of these seems to denote the dominant sound of the word represented (e.g., *n* from *nt*, “water”; *dz* from *w’dzyt*, “cobra”). About eighty signs are biliteral and seventy trilateral. These phonograms often followed an ideogram, in effect “spelling out” its value, thus accompanying the sign for “pyramid,” *mr*, could be the two consonant sign *mr* and the

Writing in the Middle East, Fig. 2 Egyptian hieroglyphs: $mr + m + r + \text{pyramid} = \text{"pyramid"}$

“alphabetic” signs *m* and *r* (Fig. 2). In addition, a range of determinative signs marked categories of terms, the best known being the oval cartouche enclosing pharaohs’ names. Problems in representing foreign names in the early second millennium BCE led to a special combination of signs to produce syllabic spellings, called “group writing” or “syllabic orthography.” Egyptian scribes normally wrote on papyrus which decays rapidly when buried except in very dry situations, so most of their work is lost. Enough survives to show that, although appearing needlessly complex, the Egyptian writing system could express as wide a range of ideas as the Babylonian. Its complexity meant that it remained a specialist skill, practiced by, it is estimated, less than 1 % of the population.

Other Ancient Scripts

The second millennium BCE – the Middle and Late Bronze Ages in archaeological terms – saw a proliferation of writing systems. In Anatolia, the Indo-European-speaking Hittites invented a hieroglyphic script for writing the Luwian language, about 1600 BCE. It is known from stone monuments, seals, and a few documents engraved on lead strips, but it is likely it was written more extensively on wooden panels, now perished. It has a basic syllabary of 70 consonant + vowel signs, a few more complex syllabic signs, and 78 logograms for commonly occurring terms (e.g., king, country) and so is similar in concept to the Cretan scripts (see below). The values of the syllabic signs appear to derived acrophonically from the initial syllable of the word each picture depicted. After the Hittite empire ended ca. 1200 BCE, smaller

kingdoms in Turkey and north Syria continued to write with the hieroglyphs until the seventh century BCE.

Similar to the Hittite hieroglyphs are the scripts found in Crete, the Cretan hieroglyphs and, perhaps descended from them, Linear A and Linear B. Only the last has been convincingly deciphered, revealing a simple syllabary of 54 consonant + vowel signs and five vowel signs, with numerous logograms which sometimes have their names written syllabically beside them, all recording an early form of Greek. Linear B was scratched awkwardly on clay tablets and was probably also written on wax tablets and other perishable materials. Apparently an offshoot of Cretan writing is the Cypro-Minoan system current in Cyprus in the Late Bronze Age, with rare examples found in the Levant. Like Linear B, surviving examples are on clay, but impressed with a stylus rather than scratched. They seem to record notes of ownership or delivery and longer compositions, but the script remains unread. Later in the first millennium, the Cypriot syllabary of 50 consonant + vowel signs and five vowel signs survives on stone, pottery, and coins. It is clearly a continuation of the Cypro-Minoan signs, probably applied to a different language, and can be read, thanks to texts with parallel versions in Greek.

A clay disk found at Phaistos in Crete is a unique representative of a pictographic script impressed on the surface by 45 separate dies in various arrangements, a precursor of printing. It may have been brought to Crete from Turkey, but without other examples, there is little likelihood that it can be understood. Its authenticity is questioned.

At Byblos, north of Beirut, a dozen documents were unearthed inscribed with signs evidently forming a large syllabary of 114 signs, fairly clearly based upon the Egyptian hieratic script. These “pseudo-hieroglyphs” of the mid-second millennium BCE await convincing decipherment. There are other, isolated, specimens of writing systems which cannot yet be read. Short texts scratched on clay tablets about 1200 BCE at Tell Deir ’Alla in the Jordan Valley are reminiscent of Cretan Linear B, but clearly not the same script.

The Alphabet

Out of this medley of scripts, one arose early in the second millennium BCE which would ultimately have the greatest impact since the invention of writing. A scribe working in the Levant, perhaps in Byblos, found none of the scripts available to him, Egyptian and cuneiform, suitable for registering his West Semitic language, so he created a system in which each sign stood for a major consonantal sound (phoneme). It seems that he drew a series of simple pictures and used each to stand for the initial sound of its name, thus “door” = d (the acrophonic principle), yielding between 20 and 30 signs. In the West Semitic languages (e.g., Canaanite, Aramaic, Hebrew, Phoenician), no word began with a vowel, and it proved possible to represent the languages adequately without signs for vowels, so at first they were not marked at all. That continues to be basically true for Arabic and Hebrew today. The system was not, therefore, a true alphabet, which should have a sign for each major sound in the language, whether consonants or vowels, but the term can be applied to it and its descendants for convenience. The scribe was accustomed to the Egyptian practice of writing with ink on papyrus and followed the Egyptian direction, writing from right to left, as Arabic and Hebrew are still written. The use of perishable papyrus sheets and wooden tablets coated with wax means that most examples of this Canaanite Linear Alphabet are lost. A few specimens scratched on metal, stone, and pottery have been found at Middle Bronze Age sites in Canaan, and two were discovered on a rock at Wadi el-Hol on the desert road across the bend of the Nile north of Thebes. The date of these two is debatable, but they certainly belong to a very early stage in the history of the script. More extensive examples come from the area of turquoise mines at Serabit el-Khadem in western Sinai. They were apparently written in the middle of the second millennium by workmen imported from Canaan who revered the mother-goddess, Egyptian Hathor, whom the Egyptians entitled “lady.” Although brief or badly damaged, so far as these inscriptions can be read, they refer to “lady” also (West Semitic *ba’alat*). The signs in

Writing in the Middle East, Fig. 3 Development of the early alphabet.

Column 1, Sinai mines, ca. 1500 BCE. *Column 2*, Canaan, ca. 1400 BCE. *Column 3*, Canaan, ca. 1200 BCE

these “Proto-Sinaitic” inscriptions appear in more developed forms scratched or painted on various objects from Late Bronze Age Canaan, and by about 1000 BCE they are almost standardized across the Levant, their number reduced to twenty-two, as examples from Byblos and other sites show (Fig. 3).

Two or three centuries earlier, scribes at Ugarit (now Ras Shamra) on the coast of Syria, trained in Babylonian tradition, realized the Canaanite Linear Alphabet was better suited to their West Semitic language than Babylonian cuneiform and imitated it by creating a cuneiform “alphabet” of twenty-seven signs, then adding three to mark sounds necessary for recording the completely different Hurrian language. Scribes at Ugarit used their script to write every type of text – letters and administrative documents, rituals, legends, and myths – on clay tablets. Their survival in the ruins of the city illustrates the sort of documents which it can be surmised were written also in Canaan, but they have perished. A very few pieces of Ugaritic writing from other sites in the Levant, as far south as Beth Shemesh west of Jerusalem, demonstrate its spread, but the script disappeared with the collapse of the Late Bronze Age city-states.

It was the Canaanite alphabet that survived the chaos at the end of the Late Bronze Age to be adopted widely. One form spread into Arabia where it became the North and South Arabic scripts, the former being known mainly from graffiti which shepherds and travelers left on rocks from the sixth century BCE to the Islamic period, the latter being attested in thousands of inscriptions on stone in the Yemen and Hadhramaut from the ninth century BCE until the seventh century AD. An offshoot of the South Arabic script

survives in the Ethiopic alphabet which has augmented the letters to mark vowels. The other form of the Canaanite alphabet was adopted by the new West Semitic-speaking kingdoms and eventually eclipsed all other writing systems in the region. The Israelites occupying Canaan found the script appropriate for Hebrew (except that it did not provide two signs to distinguish the phonemes *s* and *š*). They used this “Phoenician” or “Old Hebrew” alphabet until the Persian period, continued it for some literature, and revived it for nationalistic purposes in the Roman period. Aramaean kingdoms wrote their language with the same alphabet, despite the lack of signs to distinguish certain sounds (e.g., *t* and *ṭ*). Already in the ninth century BCE Aramaean scribes gave some characters a double value, noting both consonants and long vowels (e.g., one sign for *w* and *û*, one for *y* and *î*). Under the Persian Empire (539–331 BCE), the Aramaic language and form of script, which had been spreading widely under Assyrian and Babylonian rule, became the common vehicle of administration from the Indus to the Aegean, from the Black Sea to Egypt and the Red Sea (Fig. 4). The Jews used it for writing Hebrew, and, slightly developed, it has been the Hebrew alphabet ever since. Aramaic speakers in southern Turkey, in the area around Urfa and Haran, derived from it the forms of cursive script known as Syriac (Estrangelo and Serto) still read among Christian churches of the Middle East. Another form arose in the caravan city of Palmyra (first to third centuries AD.). Most significantly, Nabataean Arab tribes in southern Syria and Jordan began to write with the Aramaic alphabet in the last centuries BCE, and their cursive letters, known from a few papyri surviving dehydrated in caves near the Dead Sea and some other examples, are clearly the origin of the Arabic alphabet (Fig. 5). Thus the modern Arabic and modern Hebrew alphabets have the same ancestor. However, in the cursive Nabataean of the early Christian centuries, the shapes of some letters had become almost indistinguishable (e.g., *r* and *z*), and the Arabic language distinguished more consonantal sounds than the Aramaic alphabet marked, so dots were added above or below certain letters to distinguish some and to create new ones. In Syriac,

Writing in the Middle East, Fig. 4 Letters used in Hebrew handwriting ca. 600 BCE (1), Aramaic writing on stone, ca. 400 BCE (2) and on papyrus or leather, ca. 400 BCE (3)

Writing in the Middle East, Fig. 5 Letters in forms used in Hebrew handwriting, first century (1); Nabataean inscriptions, first century (2); Nabataean documents, second century (3); early Arabic (4)

Arabic, and Hebrew, besides some signs for consonants marking long vowels as well, small marks were added in the early Middle Ages above, below and occasionally within the letters to indicate all the vowels necessary for public reading of sacred texts such as the Gospels, the Torah, and the Qur'an. As Islam spread, it carried the Arabic script with it, and so it came to be applied to non-Semitic languages. For Persian, additional diacritical marks were placed on four letters to mark Iranian phonemes, and for Ottoman Turkish, modifications were needed for six. In 1928, in the Kemal Atatürk's modernization program, the Ottoman script was replaced with roman letters, augmented by diacritical marks to 29 characters (Daniels & Bright, 1996).

The Aramaic, Hebrew, and early Arabic scripts are known today from haphazard collections of inscriptions on stone and other hard surfaces and from rare groups of texts on papyrus, mostly found in Egypt. The reduced number of signs, 22–28, made the tasks of writing and reading simpler than for Babylonians, Egyptians, or Hittites, and so more people may have learned to read and write,

Writing in the Middle

East, Fig. 6 Semitic alphabetic script. *Column 1*, Phoenician, ca. 1000 BCE. *Column 2*, Moabite, ca. 830 BCE. *Column 3*, Greek, ca. 700 BCE

but widespread literacy did not result. For most people, there was no need for either skill, and if they had the need, they could find a professional scribe. Nevertheless, there is some evidence for a proportionately wider distribution of writing in ancient Israel than in neighboring lands (Millard, 1995).

On the coast of Lebanon, scribes in the Phoenician cities (Tyre, Sidon, Beirut, Byblos) continued to write with the Canaanite Linear Alphabet. Their products are almost entirely lost, only a few texts on stone, metal, and potsherds surviving. It was from them that the Greeks learned it. Greek could not be written intelligibly without marking vowels (otherwise there was no way to write the Greek word for “no,” *ou*), so signs for Phoenician, Semitic, phonemes alien to Greek were given new values as vowels, partly in line with the use of some consonants to mark long vowels in Aramaic (e.g., *w* for *û*, *y* for *î*). That yielded the first true alphabet (Fig. 6).

Writing: Maya Writing

Tom Jones

Some dozen or so writing systems have been identified as having been in use at one time or another in ancient Mesoamerica, all sharing a number of general traits that include (1) pictographic signs, clearly derived from things seen, used in combination with wholly abstract signs, the derivations of which remain obscure; (2) a reading order that generally proceeds from top to bottom and from left to right; (3) a vigesimal number system (base 20) with a dot representing the unit, generally in conjunction with individualized signs for numbers of higher orders of magnitude, though in certain areas, in conjunction with bars for “5” and other signs for “0” to express higher numbers; and (4) a shared, compound, cyclical calendar of 260×365 (18,980) days’ duration, expressed with readily identifiable calendrical elements such as numbers, day names, year signs, and periods of various magnitude.

The most sophisticated writing system – and certainly the most intriguing – of Mesoamerica, and that which will serve as the basis for this discussion, is the “hieroglyphic” writing of the Maya region. Examples of Maya hieroglyphic writing are known from many sources: from carved monumental inscriptions in stone and wood, painted stucco-coated, screen-fold, paper books, or “codices”, painted and carved ceramic pots, cups, bowls, and dishes, and from other portable artifacts of stone, shell, ceramic, and bone. The visual style, syntax, and content of the writing was shaped by both the nature of the medium upon which it appeared and the message to be conveyed.

Though open to doubt for many years, there is no question today of the Maya writing system not being true writing. It follows linguistically logical rules of syntax, phonetic construction, and semantic expression, although with the same

T-numbers

Writing: Maya Writing,
Fig. 2 Affixes with
T-numbers

willful departure from those rules as that of creative writers of our own culture – even, at times, to the point of whimsical defiance. The Maya hieroglyphs were capable of accommodating the full range of both the sounds and the syntactical structures of spoken Mayan. Indeed, the relatively narrow range of subject matter of extant Maya writing is surely more of a reflection of its differential survival on imperishable artifacts than of any limitations in the writing system itself.

The typical Maya monument inscription is composed of a number of tightly formed glyph-blocks arranged in vertical columns and horizontal rows, with the glyph-blocks formed of glyphic elements of two general sorts: relatively large ones – known as “main signs” – generally positioned at the center of glyph-blocks and occupying most of the area (Fig. 1), and smaller

ones – known as “affixes” – often positioned before, atop, after, or beneath the main signs, and sometimes (in the absence of a main sign) forming clusters of their own (Fig. 2). In his 1962 *Catalog of Maya Hieroglyphs*, Eric Thompson attempted a classification of all the known glyphs of his time, assigning to “affixes” the numbers 1–370, and to “main signs” the numbers 501–856, with what he called “portraits” receiving the numbers 1000a–1087. The study and discussion of Maya writing have benefited enormously by the preferred use of these *T*-numbers (as they are called) over the arbitrary nicknames and labored descriptions of individual glyphs that once necessarily dominated their study.

Nevertheless, epigraphic study since the publication of Thompson’s *Catalog* has shown that this main sign/affix distinction is an artificial one.

Writing: Maya Writing,
Fig. 5 Reading order for
 the elements within a
 glyph-block

some 77 consonant-vowel (cv) syllables, leaving undetected but 23 of the 100 probable sounds employed in the ancient script. At the same time, in addition to the signs for the 20-day names, about 90 glyphic elements have been demonstrated to represent consonant-vowel-consonant (cvc), or even more complex, morphemes. Thus, words can be recorded by using a single morphemic sign (should there exist one that signifies the desired word), by assembling a phonetic construction from cv-signs that sound it out, in which case the final vowel sound is dropped, or by combining the two, perhaps using a cv-sign as a (silent) phonetic complement to reinforce the pronunciation of the intended word.

In addition to the aforementioned options available to the Maya scribe, there were four further features of the writing system:

1. Allographs are multiple signs that were used interchangeably to express the same phoneme. The sound *u*, for example, could be expressed by any one of at least a dozen different allographs (Fig. 6a).
2. Puns are single signs used to express homophonous words of multiple semantic value. As an example, the Mayan word *chan* means “snake”, “sky”, and “four”. The glyphs for these three meanings could be used interchangeably to convey the sound *chan*, with the intended semantic value, which was sometimes multiple, to be inferred from the context (Fig. 6b).
3. Polyvalent signs are single signs of multiple phonetic and/or semantic value which, again, are best understood from

their context. Thus when the sign T528 appears framed by the day-name cartouche (serving as a semantic determinant), it is understood to represent the name of the day *Kawak*; when it appears suffixed with T116, the sign for **ni** (serving as a phonetic complement), it is understood to represent the term **tun** (“stone” or “year”); and when it appears with no affixes, it *usually* represents the syllable *ku* (Fig. 6c).

4. Head variants are main signs modified from their generally rounded forms into the profile heads of persons or monsters that retain their diagnostic markings (Fig. 6d).

The range of possible sizes of the various glyphic elements, their substitutability and variety of appearance (anthropomorphic, zoomorphic, and abstract), their use as cv syllables, cvc morphemes, and phonetic complements, all go toward accounting for the rich variety of visual expression that characterizes the Maya hieroglyphic writing system. Though many words could be written with a single glyph, those same words could also be expressed in other ways. As an example, the word for *balam* (jaguar) was variously expressed by using the sign that represents both the word and the concept (Fig. 7a), by using the signs for the syllables *ba*, *la*, and *ma* (Fig. 7b), by using the sign for **BALAM** with *ma* as a phonetic complement (Fig. 7c), or by using the **BALAM** sign with both **ba** and **ma** complements (Fig. 7d).

Similarly, *pakal* (shield) was expressed by using a sign that portrays a shield (Fig. 8a), by the signs

Writing: Maya Writing,

Fig. 6 (a) Ten allographs for the phoneme *u*. (b) Three signs for chan: “sky”, “snake”, and “four”. (c) Polyvalency of T528, as the day-name *Kawak*, the phoneme *ku*, and with phonetic complement *ni* to spell **TUN**-(ni). (d) Head variants for the phonemes **pa** and **ba**

for the three syllables *pa*, *ka*, and *la* (Fig. 8b, c), or by the **PAKAL** sign with a *la* phonetic complement (Fig. 8d). It will be noted that, in spite of their difference in visual effect, both the second and third of these examples are phonetic constructions of the syllables *pa-ka-la* – the second example substituting a head variant of the more usual *pa*-glyph.

Despite these general principles, there were words for which there was no single sign and the organization of which often defied the general upper-left to lower-right reading order. The word **yichnal** (together with) is a particularly interesting example of such a construction, in part because it always includes the previously mentioned **-NAL** ending superfixed to its main sign (Fig. 9). The latter might be either the standard sign for phonetic *chi* or the “torso-and-left-arm”

sign that represents the sound **YICH**. The several ways of recording **yichnal**, with the elements read in the usual order, were **yi-NAL-chi-la** (Fig. 9a), **yi-NAL-chi** (Fig. 9b), **yi-NAL-YICH** (Fig. 9c), **NAL-yi-chi** (Fig. 9d), **NAL-YICH-la** (Fig. 9e), **NAL-YICH** (Fig. 9f), and **NAL-yi-chi-la** (Fig. 9g).

Among the tasks to which a Maya scribe might be called upon to apply his skills was the execution of commissions to inscribe in stone the dynastic history and military achievements of his city’s royal family. Commissions of this sort would typically involve the recording of a variety of genealogical relationships such as *Ah Balam yal Na Chan* (Sir Jaguar is the child of Lady Sky), where the two names are separated by a glyph-block that defines their relationship, with the subordinate person named first (Fig. 10a). A military

Writing: Maya Writing, Fig. 7 Four ways of spelling *balam* (jaguar)

Writing: Maya Writing, Fig. 8 Four ways of spelling *pakal* (shield)

encounter might be expressed with two phrases such as *Chukah Pakal*. *Pakal u bak Ah Balam* (Pakal was captured. Pakal was the captive of Sir Balam), the first being a typical verb-initial Mayan sentence followed by the subject, the second defining another relationship with the identical syntax as the earlier example (Fig. 10b). Accession to political office might be recorded as *Chumwan ti ahawel Ah Balam* (Sir Jaguar was seated in the Lordship), in another typical verb-initial Mayan sentence where a positional verb is followed by a prepositional phrase with the subject named last (Fig. 10c). Were our scribe to turn from his work on public monuments to the designing of a personal book for and about Lady Sky, he might record such sentences as **Sinah u**

chuch Na Chan (Lady Sky strung her warpboard) or **Och-i ti te' Na Chan** (Lady Chan wove at the post), the first a verb-initial sentence with a transitive verb followed by a possessed object and the subject (Fig. 10d), and the second a verb-initial sentence with the verb followed by a prepositional phrase and the subject (Fig. 10e). It should be clear from the preceding examples of inscriptions on public monuments that Maya hieroglyphic writing is indeed a true writing system, fully capable of recording the language it represents.

However, for all of the marvelous achievements of recent Maya epigraphy, much work remains. Many glyphs are undeciphered and problems still linger amongst glyphs for which

Writing: Maya Writing, Fig. 9 Seven ways of spelling *yichnal* (together with)

solutions have been offered. An understanding of the kinds of difficulties encountered by epigraphers in deciphering individual glyphs can be gained from a close look at a fairly common lordly title, the five basic forms of which preclude ready demonstration of their homophony, and suggest instead the presence of both phonetic and semantic substitutions. Known to scholars as the “penis” title, the three most widely distributed forms consist of a main sign that has the appearance of a profile representation of male genitalia infixed with the sign for *sha* and suffixed alternatively with *-ti* or *-ta* affixes (Fig. 11a–f). Desirable as it might be to have a homophonous reading for the three forms – and their interchangeability in the texts is beyond doubt – the conflicting sounds of their initiating prefixes would appear to preclude any such solution. One form is prefixed with the sign for *yo-* (Fig. 11a, b), and second with *to-* (Fig. 11c, d), and a third with both *yo-* and *to-* (Fig. 11e, f).

Because these substituting sounds are prefixed, the words that they signify must begin with the sounds *yo*, *to*, and *yoto*, respectively. The likelihood that the male genitalia-main sign is intended to convey the sound *AT* (the pan-Mayan word for penis) is confirmed by the interchangeable *-ti* and *-ta* suffixes that invariably accompany it, apparently serving as phonetic complements. If, then, the *sha* infix is read before the presumed sound of the main sign, the sound sequence should be *sha-AT* (ti/ta), or the not too promising *shat*. However, if the previously mentioned *yo-* prefix is added to this, the result is *yoshat*, or *yosh-at* (scarred penis); if *to-* is added, the result is *toshat*, or *tosh-at* (bled penis); and if *yo-to* is added, the result is *yotoshat*, or *yotosh-at* (very scarred penis). Though any such title might strike those of us with a background in Western European culture as bizarre, nevertheless given the wealth of evidence for the presence of penis-perforation ceremonies in which Maya lords

Writing: Maya Writing,
Fig. 10 The construction
 of Maya sentences

engaged and the occasional portrayal of a scarred penis on figures in Maya art, the existence of a hieroglyphic form of a title that testified to a lord's personal sacrifice perhaps ought not to surprise anyone.

Understanding of the remaining two of the five forms which this title assumes is less certain. The first of these is a head variant that is always superfixed with **to-** and postfixed with **-ti** or **-ta** (Fig. 11g, h), suggesting the possibility that the head represents the full term **TOSHAT**, or **TOSH-AT**, with both affixes serving as phonetic

complements. The second (of which there are but two examples) is a phonetic construction that is in clear contradiction to the previously discussed **yosh-at** renderings: one reads **yo-ta-ta**, the other **yo-a-ta-ta** (Fig. 11i, j). Not only is the **ta** sound doubled in each, but there is also nothing present that could be construed to represent **sha**, the necessary middle consonant of **yosh-at**. Nor is there an easy resolution of this difficulty; either the previously proposed **yosh-at**, **tosh-at**, and **yotosh-at** readings are in error and the arguments in support of them faulty, or the Maya scribe that

Writing: Maya Writing, Fig. 11 Semantic substitutions in the “penis title”

recorded the two purely phonetic constructions (they are both at Copan) failed to include all the sounds of the word he intended to record, or – and this is a solution that preserves both the earlier **yosh-at**, **tosh-at**, and **yotosh-at** readings and the literary reputation of the Copan scribe – the scribe deliberately omitted the middle (**sh**) consonant, as is thought to have been done with other two-syllable words. One can only hope that further research and further field discoveries will someday throw stronger light on this and similar difficulties. Nor has there ever been a time when Maya scholars were more optimistic about the possibilities of their ultimate decipherment of this poetically conceived, strikingly beautiful, and wonderfully complex ancient writing system.

Postscript. Since the preceding was written and submitted to the publisher, an alternative to the reading of the penis title presented above has been proposed by Linda Schele based upon a recently recognized example that appears to include a sign for the sound **ho**. Schele proposes a **yoh-at** reading for the **yo**-prefixed form and phonetic construction, a **toh-at** reading for the **to**-prefixed form (and its head-form), but is silent

regarding the **yo-to**-prefixed form. This should convey some idea of the difficulties raised in the closing paragraphs above.

Xiahou Yang

Ang Tian Se

Much of the life story of Xiahou Yang remains unknown, and so is the date of *Xiahou Yang Suanjing* (Xiahou Yang's Mathematical Classic), a text purported to have been written by him. When Zhang Qiujiang wrote his mathematical text some time between AD 468 and 486, he criticized the inaccuracy of the solution of a "rectangular granary" problem from Xiahou Yang's work. This shows that Xiahou Yang was either Zhang's contemporary or his predecessor. The text also mentioned a change of volume standard which took place in AD 425, thus affirming that both Xiahou Yang and Zhang Qiujiang were mathematicians of the Northern Wei dynasty (AD 386–535) and that the text of Xiahou Yang was written between AD 425 and 468.

The *Xiahou Yang Suanjing* appeared to be an important text as it was selected by Yu Zhining in AD 656 for use in the National Academy during the Tang dynasty (AD 618–906). In AD 662, the text was annotated by ► [Li Chunfeng](#) along with nine others for use in the imperial examinations. However, when the text was reprinted and included as one of the *Ten Mathematical Classics* in AD 1084 during the succeeding Song dynasty, it appeared to have been rewritten, probably by

Han Yan (AD 780–804) in the Tang dynasty. This is evident in the text itself where a number of statutes governing the Tang systems of land, taxation, and official hierarchy were mentioned.

The present version of the text has three chapters consisting of 82 problems. It deals with percentages and roots, as well as the ordinary logistic operations. Xiahou Yang seemed to have understood both the positive and negative properties of powers of 10 such as $10,000 = 10^4$ and $1/10,000 = 10^{-4}$. He also seemed to have understood the developed conception of decimals. In one problem, he suggested the conversion of the last four metrological units to simply writing down the numbers in four successive places as they would be expressed in modern decimal notation. Though Xiahou Yang provided some modified forms for multiplication and division in some problems, he also repeated some inaccurate solutions found in the *Wu Cao Suanjing* (Mathematical Classics of the Five Government Departments) of the fourth century, the most glaring of which was the rule for determining the area of a figure consisting of two congruent trapezoids and a quadrilateral.

Xu Yue

Ang Tian Se

Xu Yue, whose literary name is Gonghe, was a native of Donglai (in present Ye District, Shandong Province). Very little is known of his background except that he was a follower of ► [Liu Hong](#), an eminent mathematician and calendar expert of the second century. He studied mathematics and astronomy under Liu Hong and had frequent discussions with him and the Astronomer-Royal of the Astronomical Bureau on matters pertaining to calendrical astronomy. He was said to have written a commentary on the ► [Jiuzhang Suanshu](#) (Nine Chapters on Mathematical Art) and a mathematical text known as *Shu Shu Ji Yi* (Memoir on Some Traditions of Mathematical Art) around AD 190. The commentary had long been lost while the *Shu Shu Ji Yi* was handed down with a commentary written by Zhen Luan (fl. AD 570). There are a number of Buddhist references in Zhen Luan’s commentary.

The *Shu Shu Ji Yi* was written in a terse and obscure style, tinged with Daoism and divination. Xu Yue mentioned that the mathematics he learnt

from Liu Hong was that transmitted directly by a Daoist adept called Tian-Mu Xiansheng (Mr Eye-of-Heaven). The text mentions 14 old methods of calculation, many of them bearing the names taken from the Yijing (I Ching, Book of Changes). Of special interest is one called “ball-arithmetic,” a trough-and-ball instrument similar to an ► [abacus](#). Three other methods also involved the use of “balls”. The first involved the use of one ball per column moving up and down a board or a trough. The second used two balls of two different colors, one relating to a y-axis on the left and the other to a y-axis on the right. Both these methods seem to have utilized a map-like grid of lines, similar to that of Cartesian coordinates. The third utilized balls of three different colors for use on three horizontal positions only. Joseph Needham has commented that this system of calculation “shows an interesting appreciation of coordinate relationships.”

Another interesting aspect of *Shu Shu Ji Yi* is its reference to large numbers and to their representation in three forms of arithmetical series. Xu Yue called them the “upper, middle, and lower” classes of numbers, all beginning with *wan* (10^4). The three classes of large numbers may be summarized in Table 1.

The *Shu Shu Ji Yi* also gives a description of the “calculations of the nine balls”, which according to the commentary provided by Zhen Luan was a simple magic square of order 3.

Though brief, obscure, and couched in religious nuances, Xu Yue’s *Shu Shu Ji Yi* was selected as a prescribed mathematical text for imperial examinations during the Tang dynasty (AD 618–906). It was a difficult text, and candidates had to learn it by heart in order to pass the examinations.

Xu Yue, Table 1 The three classes of large numbers following Xu Yue

	wan	yi	zhao	jing	gai	zi	rang	gou	jian	zheng	zai
Upper	10^4	10^8	10^{16}	10^{32}	—	—	—	—	—	—	—
Middle	10^4	10^8	10^{12}	10^{16}	10^{20}	10^{24}	10^{28}	10^{32}	10^{36}	10^{40}	10^{44}
Lower	10^4	10^5	10^6	10^7	10^8	10^9	—	—	—	—	—

Yaḥyā ibn Abī Maṣṣūr

Emilia Calvo

Yaḥyā ibn Abī Maṣṣūr was an astronomer from an important family of Persian scientists (his father was an astrologer). Yaḥyā spent his life casting horoscopes and trying to determine the positions of the stars with precision. He began working for al-Faḍl ► [ibn Sahl](#), the vizier of the Caliph ► [al-Ma'mūn](#) and, after his death, for the Caliph himself. He taught the ► [Banū Mūsā](#) and died near Aleppo, Syria in AD 832.

Yaḥyā was the director of a group of astronomers working under the Caliph al-Ma'mūn, in the observatories of Shamāsiyya in Baghdad and Dayr Murrān in Damascus. The scholars included in the group were al-Marwarrūdhī, ► [al-Khwārizmī](#), Sanad ibn 'Alī, the Banū Mūsā and ► [al-Jawharī](#). They measured 1° of meridian by using two different procedures. The results of the observations were recorded in various *zīj*es (Astronomical Handbooks with Tables), one of which is the ► [Zīj al-mumtaḥan](#) (The Tested Tables) that was written by Yaḥyā himself. The observations ended when Yaḥyā and the Caliph died almost simultaneously.

Yaḥyā's *zīj* is preserved in one manuscript (Escorial 927) which is badly bound and comprises many folios that are not from Yaḥyā's work. It contains an explanation of calendars and chronological eras. The elements to calculate planetary longitudes are the result of the combination of Hindu-Iranian and Ptolemaic methods.

Yaḥyā's tables exerted a great influence on later astronomers: Thābit ibn Qurra wrote an introduction to them, Ibn Yūnus adapted them to Egypt, and ► [Ibn al-Zarqāllu](#) derived from them certain values such as the inclination of the ecliptic.

Yang Hui

Ho Peng Yoke

Yang Hui (fl. 1261–1275), a native of Qiantang (in modern Hangzhou), ranks with ► [Qin Jiushao](#) (ca. 1202–ca. 1261), Li Zhi (1192–1279), and Zhu Shijie (fl. 1280–1303) as one of the four great mathematicians during the golden age of mathematics in thirteenth-century China. Of the four we know the least about Yang Hui's life, yet he has left behind a much larger number of writings than the others, showing that his mathematical interest also covered a wider field than any of his contemporaries known to us.

In the year 1261 he wrote the *Xiangjie jiuzhang suanfa* (Detailed Analysis in the Mathematical Rules in the Nine Chapters and Their Reclassifications). The original work comprised 12 chapters and an Appendix, which included an arrangement of numbers which he attributed to the eleventh-century mathematician ► [Jia Xian](#) and which in 1654 came to be known as Pascal's Triangle. Although the original work is no longer extant in its entirety, sections of it are quoted in the early fifteenth-century Imperial Compendium, the *Yongle dadian*.

Yang Hui also wrote the *Xiangjie suanfa* (Mathematical Methods with Detailed Explanations) on the processes of multiplication and division. Then in 1262 he produced an elementary text for beginners called the *Riyong suanfa* (Everyday Mathematics). In 1274 he wrote the *Chengqu tongbian suanbao* (Precious Reckoner for Variations in Multiplications and Divisions). In 1275 he wrote the *Tianmou bilei chengqu jiefu* (Practical Rules of Arithmetic for Surveying). The same year he assembled some old and forgotten materials and published the *Xugu zheqi suanfa* (Continuation of Ancient Mathematical Methods for Elucidating the Strange Properties of Numbers). This is the earliest Chinese monograph that we have on magic squares.

The last three works mentioned above were published together in 1378 under a single title *Yang hui suanfa* (Yang Hui's Mathematical Methods). A full study of this book was undertaken by Lam Lay Yong in 1977.

Like his contemporaries Yang Hui used numerical equations of higher degree. His *sanchengfang* (quartic root) method is very similar to that rediscovered by Horner and Ruffini in the early nineteenth century. He employed freely the concepts of "dummies" and substitution in his algebra. At the same time his attention was on the practical side, always trying to provide the quickest working method. It seems that Chinese mathematicians were quite active during the eleventh and twelfth centuries, but none of their writings remains. At least we have come to know something about them through Yang Hui's writings.

Ya'qūb ibn Ṭāriq

Jan P. Hogendijk

Ya'qūb ibn Ṭāriq was one of the earliest astronomers in the Islamic tradition. Very little is known about his life. He worked in the last quarter of the

eighth century, when Arabic astronomy was not yet influenced by Ptolemy's *Almagest*. The works of Ya'qūb are lost, but some fragments have come down to us in later astronomical treatises and handbooks. The following information is based on such fragments. Ya'qūb authored three works:

1. A ► *zīj* (Astronomical Handbook with Tables), which was influenced by Indian and pre-Islamic Persian astronomy. For example, he took the zero meridian and the mean motion of the planets from India, and he seems to have adopted the planetary equations from a Persian source. In the lunar visibility theory, Ya'qūb used an Indian method to measure the width of the lunar crescent in "digits." His lunar visibility table is extant.
2. The *Tarkīb al-Aflāk* (Composition of the Heavenly Spheres) is summarized in some detail in al-Bīrūnī's *India*. In this work Ya'qūb discussed the size of the earth and the distances of the planets.
3. In the *Kitāb al-'Ilal* (Book of Reasons), Ya'qūb explained trigonometrical rules, which he probably used in his *zīj*. A few citations of this work are given by ► *al-Bīrūnī*. Ya'qūb based his trigonometrical calculations on a sine table with base 3,438.

Yavaneśvara

Manu V. Devadevan

Archive India Institute, Bhubaneswar, Odisha, India

Yavaneśvara was an astronomer of western or north-western India who lived in the mid-second century CE. He is said to have rendered a Greek treatise on astrology into Sanskrit. Sphujidhvaja, who wrote the *Yavanajātaka* (the Ionian Horoscopy) in the year 269–70 CE, says that his work is a verse rendition of Yavaneśvara's prose text.

Yavaneśvara (lord of the Yavanas or Ionian Greeks) seems to have been a title in use among the ruling elites of western India in the second and third centuries, patronized by the so-called western Kṣatrapa rulers. India's contacts with Greece were established after Alexander invaded the Indus valley in 327–25 BCE and left behind several satraps to administer the region. Following the departure and demise of Alexander, some of these satraps disintegrated, while others developed into principalities in their own right. Greek officials like Megasthenes, Daimachus, and Nearchus traveled in different parts of India, and there were Greek embassies in the court of the Mauryan rulers Chandragupta Maurya and Bimbisāra (between ca. 321 and 273 BCE). Within a short period, regular contacts between India and the west were to be seen. The inscriptions of the third Mauryan king Aśoka (ca. 250 BCE) refers to western rulers like Antiochus Theos of Syria, Ptolemy Philadelphus of Egypt, Antigonos Gonatas of Macedonia, Magas of Cyrene, and Alexander of Epirus. Exchange of knowledge between the two regions might also have commenced in this period. Bimbisāra is known to have requested his Greek counterpart to depute a sophist to his court. Greek influence is perhaps best noticed in the field of sculpture, especially of the Gāndhāra and Mathura schools. Yavaneśvara's work is a result of these historical encounters.

The *Yavanajātaka*, which is the most important source providing access to the work of Yavaneśvara, is a treatise in 4,000 verses, of which only 2,300 survive. These are divided into 72 sections. Among the areas covered in the extent text are zodiac signs, planetary movements, and their influence on human beings, predictions, the making of horoscopes, omens, dreams, military astrology, and so on. Influence of the Babylonian theory of planetary motions is seen in this work.

The work of Yavaneśvara seems to have laid the foundations for a Yavana school of astrology in India. This is evident from texts like the *Yavanapārijāta*, the *Bhāvadīpika* (also called *Bhāvādhyāya*), the *Nakṣatracūḍāmaṇī* and two texts bearing the name *Candrābharaṇahorā*, one popular in northern India and the other in the south. In addition, the influence of Yavaneśvara is also seen in works like Varāhamihira's *Brhājyātaka* and Kalyāṇavarman's *Sārāvalī*.

Also see “► [Sphujidhvaja](#)” and “► [Astrology in India](#).”

Yinyang

Wei Chen
Department of Mechanical Engineering,
Northwestern University, Evanston, IL, USA

Yinyang is a Chinese term composed of two words. *Yin* means the shade and *yang* the sunshine. It is the most important concept in the

traditional Chinese way of thinking, the basic concept for classification and explanation in Chinese science, medicine, and philosophy.

The word *yinyang* designates a special method for looking at things as well as for describing the phenomena of the world, including the human body. Yin and *yang* make a pair which exist together. In their coexistence, these two oppose each other in their different functions and at the same time help each other. They both contribute and are necessary to the other's existence. All phenomena can be looked at and described using the *yinyang* paradigm. This is the typical methodology of Chinese science.

The concept of *yinyang* can be compared with the Western dialectic method. However, in Chinese science this way of thinking has developed into a very complicated system of knowledge, in which *yin* and *yang* are represented in every real object. Therefore, *yinyang* is more than a way of thinking; it is also a theory that provides guidelines for human action.

The use of the concept of *yinyang* can be best illustrated by examples. The earliest example which can be found in extant Chinese ancient texts is from the Confucian classic *Yijing* (I Ching, The Book of Changes). It is not to be found in the *Yijing* proper, but in the commentaries (so-called *Yizhuan*, *I Chuan*, or the Ten Wings). It is generally accepted that *Yizhuan* was compiled during the Warring States period (the fifth to the third century BCE), so that is the earliest date we can attribute to the origin of the concept of *yinyang*. *Yizhuan* uses *yinyang* to explain the *Yijing* proper in such a way that the binary notation for every possible movement (change) in the real world is explained as representing the actual acting of the two opposing factors (or forces in the Western sense of the word) that substantiate the situation under consideration. Thus in the relation of men and women, *yang* represents man and *yin* represents woman. Likewise in the relation of heaven and earth, of sun and moon, of day and night, etc., *yang* represents the former and *yin* the latter. Furthermore, *yang* and *yin* are used to represent opposite qualities including natural attributes like hot and cold, hard and soft, bright and dark, odd

and even, as well as human dispositions like aggressiveness and submissiveness, or activeness and inactiveness.

Two points need to be emphasized here. The first is that the designation of *yang* or *yin* to an object is only effective in certain relationships. Relative to the woman, the man is *yang*. But there are other traditionally important relations that man comes into, such as that of heaven and man, of man and gods, of man and his fate, or of individual man and his family or society. In any of these, “man is *yang*” does not apply. Therefore, the traditional designation of *yang* and *yin* forms the hard core of a knowledge about the world. The second is that the use of the concept of *yinyang* is a pragmatic one. To say something or some quality is *yang* and the opposite is *yin* will be meaningful only if this designation classifies these two objects or qualities into two existing categories into which many other things or qualities are already classified. A wrong designation will make a real difference in human action when using this knowledge of classification to make a decision according to a certain theory.

According to Chinese historical records, especially the authoritative *Shi Ji* (Records of Historians) by Si Maqian (b. 145 or 135 BCE), during the Warring States period one of the six most important schools of ideas was called the *yinyang* school. It is generally accepted that, beside its political and philosophical relevance, this school brought about two important developments, which somewhat related to each other throughout the 2,000 years afterward. One is the Daoist practice of alchemy and physical immortality; the other is Chinese traditional medicine, or more accurately, Chinese body science.

From both the Chinese traditional viewpoint and from the modern Western point of view, the most important use of the *yinyang* concept can be found in the theory and practice of Chinese traditional medicine. The earliest extant medical literature was unearthed in 1973 from the Han Tomb No. 3 at Mawangtui, Changsha, Hunan Province, China. There are records which show that these texts were buried in the tomb with the dead Marquis in the year 168 BCE. In these texts the *yinyang* concept is used as the most basic

classifying concept. It is the same with the ► [Huangdi Neijing](#) (Yellow Emperor’s Classic of Internal Medicine), which contains medical essays edited in the first centuries AD. From these texts we know that the *yinyang* concept was used in Chinese medical theory much earlier than the second century BCE.

In Chinese medical theory, *yin* and *yang* are two different kinds of *qi* (literally “breath” but occasionally translated as meaning “vital force”), which function within the human body contradictorily and complementarily, and thus make the body alive. Human health is attained by keeping these two *qi* in a good, natural balance. All health problems are caused by the lost of this balance. All medical theories, diagnoses, and therapies can be understood as practical knowledge of how to classify the imbalance into a certain system of categories and how to use different means, which are classified into corresponding categories, to retrieve the natural balance. For a simplified example, two common health problems are diagnosed as *yang*-deficiency-*yin*-excess and *yin*-deficiency-*yang*-excess, which correspond to cold and heat syndromes. In diagnosis these two syndromes are related to two categories of symptoms which include every possible change in the pulse, the complexion, the tongue, the breath, the excrement and urine, etc., of the patient. In therapy, herbal medicine, or the method and location of acupuncture points are correspondingly classified.

There are two other concepts which are closely connected with the *yinyang* concept. They are the *wuxing* (five phases), which is extremely important in Chinese science, and the *taiji* (the ultimate beginning), which is more important in Chinese philosophy. The *yinyang* concept is also the basic concept used in Chinese fortune telling such as astrology (*suanming*, literally “calculating the fate”) and geomancy (► [fengshui](#), literally “wind and waters”).

Yoga

A. V. Balasubramanian

Yoga is one of the six principal systems of Indian thinking known as *darśanas*. The word *darśana* is derived from the Sanskrit root *drs*, meaning “to see.” Fundamentally, *darśana* means “view” or “a particular way of viewing.” Yoga, as one of the six *darśanas*, has its source in the Vedas. In the traditional Indian view these are called *vaidika*, or Vedic *darśanas*. These are *nyāya*, *vaiśeṣika*, *sāṅkhya*, *yoga*, *mīmāṃsā*, and *vedānta* (there are other *darśanas* that do not accept the supremacy of the Vedas, such as Buddhism and Jainism). While the source of Yoga was the Vedas, Yoga was formalized by Patañjali, one of the great Indian sages. His classic text is *Yoga Sūtra* (Aphorisms on Yoga). Although there are many

other major treatises on Yoga that postdate Patañjali's, his work is the most authoritative.

All the *darśanas* proclaim that it is their aim to help human beings achieve clarity and balance of perception and action. Yoga is unique in as much as it offers practical suggestions and guidelines to achieve this end. According to the tenets of Yoga, human beings are under the influence of *avidyā*, which is what prevents correct perceptive analysis. Sage Patañjali suggests practical ways to reduce and remove *avidyā*. In his *Yoga Sūtra*, three things are suggested to help us explore the meaning of Yoga and therefore feel *avidyā*. These are *tāpas*, *svādhyāya*, and *īśvara-pranidhāna*. *Tāpas* is a means by which we keep ourselves fit and clean. Often *tāpas* is defined as penance, mortification, and dietary austerity, but what is meant is the practice of *āsana* (postures), *prāṇāyama* (control of the breath), and other disciplines. These practices aid in the removal of impurities from our systems. In so doing we gain control of our whole system. It is the same principle as heating gold to purify it.

The next part of Yoga is *svādhyāya*, the study of the self. Where are we? What are we? What is our relationship to the world? It is not enough to keep ourselves fit; we should know who we are and how we relate to others. This is not easy because we do not have an actual mirror for our minds as we do for our bodies. We must use reading, study, discussion, and reflection as a mirror to the mind.

The third means of exploration is *īśvara-pranidhāna*. It is usually defined as “love of God” but it also means “quality of action.” We must carry out our jobs, and all our actions must be done with quality. Since we can never be certain of the fruits of our labors, it is better to remain slightly detached from them and pay more attention to the actions themselves.

Together, these three cover the whole of human action: fitness, inquiry, and quality of action. Taken together, these practices are known as *Kriyā Yoga*, the Yoga of action. Yoga is not passive. We must be involved in life, and preparation is necessary for this involvement.

Patañjali's Yoga is sometimes called *Aṣṭāṅga Yoga*, which literally means Eightfold Yoga.

These eight are *yama*, *niyama*, *āsana*, *prāṇāyāma*, *pratyāhāra*, *dhāraṇa*, *dhyāna*, and *śamādhi*.

Patañjali considers five different attitudes (*yamas*) or relationships between an individual and “the outside.” The first is *ahimsā*. While the word *himsā* means injury or cruelty, *ahimsā* means more than merely the absence of *himsā*. It means kindness, consideration, or thoughtful consideration of people or things. The next *yama* is called *satya*, “to speak the truth.” The third *yama* is *asteya*. *Steya* means “to steal”; *asteya*, the opposite, means if we are in a situation where people trust us, we will not take advantage of them. The next *yama* is *brahmacarya*. The word is composed of the root *car* (to move) and *brahma* (the truth). If we move toward the understanding of truth, and sensual pleasures get in the way, we must keep our direction and not become lost. The last *yama* is *aparigraha*, “hands off.” *Parigraha* is the opposite of the word *dana*, which means “to give.” *Aparigraha* means “to receive exactly what is appropriate.”

Niyamas, like *yamas*, are attitudes and are not to be taken as actions or practices. The five *niyamas* are more intimate in the sense that they are the attitudes we have toward ourselves. The first *niyama* is *śauca*, or cleanliness. There are two parts to this, external and internal. External *śauca* has to do with simply keeping ourselves clean. Internal *śauca* has to do with cleanliness of the internal organs and mind. The practice of *āsanas* or *prāṇāyāma* could be an internal *śauca*. The second *niyama* is *santosa*, a feeling of contentment. The next is *tāpas*, a word we have already discussed. With *tāpas* the idea is to bring out *asuddhi*, “dirt” inside the body. *Svādhyāya* is the fourth *niyama*. As we defined it earlier, *sva* means self; *adhyaya* means study or inquiry. Actually, *adhyaya* means to go near. *Svādhyāya* means to go near yourself, i.e., to study yourself. Any study, reflection, or contact that helps us understand more about ourselves is *svādhyāya*. The last *niyama* has also been mentioned before. *Īśvarapranidhāna* means “to leave all our actions at the feet of the Lord.” Since our actions often come from *avidyā* it is possible that they might go wrong. That is why contentment is

so important. This attitude suggests that we have done our best, and can leave the fruits of our actions in the hands of something higher than ourselves.

The third *aṅga* is *āsana*. In the theory of *āsana* practice, there are two aspects, *sukha* and *sthira*. We must be comfortable and at ease (*sukta*) and we must be steady and alert (*sthira*). We must be involved and at the same time attentive. Yoga suggests ways to achieve these qualities in *āsana*. The fourth *aṅga* is *prāṇāyāma* which is conscious regulated breathing. *Pratyāhāra*, the fifth *aṅga*, involves the senses. The word *āhāra* means “food.” *Pratyāhāra* means “withdrawing from that on which we are feeding.” This refers to the senses: when the senses refrain from “feeding” on their objects, i.e., *pratyāhāra*.

Dhāraṇa comes from the root *dhr*, “to hold.” *Dhāraṇa* occurs when we create a condition so that the mind, normally going in a hundred different directions, is directed toward one point. *Dhāraṇa* is a step leading toward *dhyāna*. In *dhāraṇa* the mind is moving in one direction; nothing else has happened. In *dhyāna*, when we become involved with a particular thing and we begin to investigate it, there is a link between ourselves and this object; i.e., there is a perceptual and continuous communication between the object and our mind. This communication is called *dhyāna*. Further, when we become so involved with an object that our mind completely merges with it, that is called *śamādhi*. In *śamādhi* we are almost absent; we become one with that object.

There are many varieties of Yoga. Some people say that *dhyāna* is the means to *Jñāna Yoga*. In this context, this means inquiry about the truth, the real understanding that we attain in a state of *śamādhi*. Inquiry in which we hear, then reflect, and then gradually see the truth, is *Jñāna Yoga*. In the *Yoga Sūtra* it is said that in the state of mind where there is no *avidyā*, automatically there is *Jñāna*.

Bhakti Yoga comes from the root *bhak* which means “to serve that which is higher than ourselves.” This means an attitude of devotion. In *Mantra Yoga*, a teacher who knows us very well might give us a *mantra* which has a particular

connotation because of the way it has been arranged. If that *mantra* is repeated in a certain way, if we are aware of its meaning, and perhaps if we want to use a particular image, *Mantra Yoga* brings about the same effect as *Jñāna* or *Bhakti Yoga*. In *Rāja Yoga*, the word *Rāja* means “the king who is always in a state of bliss, who is always smiling.” Any process through which we achieve greater understanding of the mysterious and the obscure is *Rāja Yoga*. In the Vedas there are many references to the word *Rāja* in relation to *īśvara*.

It is best to explain *Laya Yoga* in a context of *samādhi*. When the meditator completely merges with the object of meditation, that is *Laya*. We merge with the object and nothing else exists.

In recent times, much has been written about Hinduism, and a lot of it pertains to and derives from the viewpoint of Vedānta. It is important to see that the viewpoint of Yoga differs in some crucial respects from the viewpoint of Vedānta. Brahman is considered the “*Pāramārthika Satya*” or ultimate truth, and the world we live in and experience through our senses is granted the status of truth at an operational level, i.e., “*Vyāvahārika Satya*.” In a sense, this carries the implication that the world is false and illusory. According to Yoga, everything we see, experience, and feel is not an illusion but is true and real. This concept is called *satvāda*.

Everything, including *avidyā*, dreams, and even fancy and imagination, is real. However, all these are constantly in a state of flux. This concept of change is called *pariṇāmavāda*. In Yoga, although everything we see and experience is true and real, changes do occur either in character or in content.

Yuktibhāṣā of Jyeṣṭhadeva

K. V. Sarma

Madras, Tamilnadu, India

Jyeṣṭhadeva (fl. 1500–1610) was a Nambūthiri Brahmin from the Ālattūr village, an important Brahmin settlement near Cochin. He was probably a student of Dāmodara, the son of Parameśvara, who also taught Nīlakaṇṭha Somayāji. His fame rests on the authorship of one of the most important texts of the Kerala school of mathematics and astronomy, the *Yuktibhāṣā* (An Exposition of the Rationale [of mathematics and astronomy]), also called *Gaṇita-nyāya-saṅgraha* (Compendium of Mathematical Rationale). It is a unique work on the rationale of Hindu mathematics and astronomy as it was understood in medieval India. It is unique in the sense that it is neither a textbook nor a commentary but a work which is wholly devoted to a systematic exposition of mathematical rationale, written in Malayalam, the local language of Kerala.

Born about 1500, Jyeṣṭhadeva probably composed the *Yuktibhāṣā* about 1530, since it is known that a little after 1534, Śaṅkara Vāriyar, another contemporary astronomer, used it in his commentaries. Another work of Jyeṣṭhadeva, the *Ḍṛṅkaraṇam*, also in Malayalam, was composed in AD 1608.

K. V. Sarma: deceased

At the outset of the work, the author states that he is attempting “to set out in full the rationale useful for understanding the planetary motion according to the *Tantrasaṅgraha* of Nīlakaṇṭha Somayāji” (b. 1444). But he actually goes much beyond that and subjects to rationalistic analysis the entire gamut of mathematics and astronomy. In fact, he takes up the treatment from the very fundamentals, the concept of numeration and the theory of numbers. The work is made up of two divisions, each one divisible into several sequential chapters.

The first deals with the following subjects: (1) the eight fundamental operations, from simple addition to the roots of sums and differences of squares, wherein several methods, including diagrammatic solutions, are offered; (2) algebraic problems; and (3) operations on fractions. The other chapters deal with (4) the general nature of the Rule of Three (direct proportion); (5) application of the Rule of Three in the computation of mean planets; (6) elaborate rationalizations of the circumference of the circle; and (7) the rationales of the derivation of the R sines, R versed sines, their addition, properties of cyclic quadrilaterals, and the surface area and volume of a sphere. Many of the rationales are demonstrated both algebraically and geometrically.

Part Two is devoted to the exposition of rationales in astronomy, including (1) the computation of mean and true planets by means of two types of epicycles, supplemented by corrections; (2) the celestial sphere, the related great circles and secondaries, the precession of the equinoxes, and the armillary sphere; (3) declination, right ascension, and related matters; (4) problems related to spherical triangles; (5) problems connected with direction and shadow; (6) computation of the rising and setting points of the ecliptic, the ecliptic having constant variation. A direct method, enunciated in Indian astronomy for the first time, is used; (7) eclipses and the attendant parallax corrections; (8) the *Vyatipāta*, which is the moment when the sun and the moon have equal declinations but in different quadrants; and (9) reduction of computed results to observation and with the phases of the moon.

Some points are of special interest in the *Yuktibhāṣā*. One is the rationale for three or four steps for true planets, although the result can also be obtained in two steps; the derivation of inverse declination and inverse right ascension; novel solutions for some of the problems on spherical triangles and on shadows; refinements for parallax corrections; and an alternate method with a novel correction for the computation of the moment of *Vyatipāta*. A noteworthy characteristic is its elucidating rationale from the fundamentals, first setting out the axioms and postulates involved and then developing the arguments and methodologies step by step.

It might also be noted here that Śaṅkara Vāriyar provided a valuable service by incorporating rationales from the *Yuktibhāṣā* into Sanskrit, the language of scholars. This he did in two elaborate commentaries called *Kriyākramakārī* on the *Līlāvātī* by Bhāskaraṇḍyā and *Yuktidīpikā* on the *Tantrasaṅgraha*, a work on astronomy by Nīlakaṇṭha Somayāji. There is also a highly corrupt rendering of *Yuktibhāṣā* into Sanskrit.

Yupana

Molly Tun

University of Minnesota, Minneapolis, MN, USA

Yupana is the name given to the counting device – or abacus – of the Incas; in the indigenous Andean language of Quechua, “yupay” means “to count.” Counting was a fundamental aspect of structuring such an extensive and elaborate civilization as that of the Incas, which reached its height in the fifteenth and sixteenth centuries with an estimated population in the millions and extending across the diverse climatic regions of northern Chile and Argentina, Ecuador, Bolivia, Peru, and the southern part of Colombia. This calculating device along with its corresponding recording device – the quipu – were the main technologies that organized the Inca population and controlled the distribution of goods and labor responsibilities. While the quipu knot records were static registries of amounts calculated and served as the authoritative voice of quantities paid, quantities due, and standard measurements and statistics, the yupana would have been the device used to calculate (but not register) those amounts later tied into quipu cords. While the knot structure of the quipu was not suitable for the manipulation of numbers nor performing repeated algorithms, the yupana is a table upon which counters (of beans, corn, pebbles, grains, or other tokens) can be freely moved, thus facilitating the execution of distinct numeric operations.

Colonial Descriptions of La Yupana

The yupana has been associated with two different artifacts: (1) the carved rock, wooden, and clay deposits of archaeological provenience and the (2) sketched figures of counting boards primarily from Guaman Poma de Ayala’s *Nueva corónica y buen gobierno*, both of which are illustrated and discussed below. The interpretation of these Inca artifacts as counting tools is supported by ample documentation of the existence of such a device in numerous colonial chronicles and texts. The Spanish missionary José de Acosta describes (without understanding) the Inca counting system:

To see them use another kind of quipu with maize kernels is a perfect joy. In order to carry out a very difficult computation for which an able accountant would require pen and ink... these Indians make use of their kernels. They place one here, three there and eight I do not know where. They move one kernel here and three there and sure enough, they are able to complete their computation quickly without making the smallest mistake. As a matter of fact, they are better at calculating what each one is to pay or give than we would know how to check with pen and ink. Whether this is not ingenious and whether these people are wild animals let those judge who will! What I consider as certain is that in what they undertake they have great advantage over us. (De Acosta, 2008, p. 211)

Archaeological Artifacts with Carved Deposits for Counting

The first archaeological finding linked to the yupana was a symmetric tablet (33 × 27 cm) found near Chordeleg (Cuenca) in 1869 exhibiting 21 carved spaces and elevated platforms on two diagonal corners (Fig. 1). Similar objects have been uncovered in the ruins of Chan Chan, between Cuenca and Sig Sig, Ancash, Caraz, Pallasca, Callejón de Huaylas, and Ica (Radicati di Primeglio, 1990, pp. 220–229). Although these objects have been classified as counting devices by certain scholars (Arriaga, 1922; Gonzales Suarez, 1878; Verneau and Rivet, 1912; Wiener, 1880), this is only one possible interpretation. At one point these carved

Yupana, Fig. 1 A carved deposit similar to the Chordeleg yupana

deposits were also believed to be architectonic models (Bastian (n.d.); Gonzales Suarez, 1878) as well as games of chance (Uhle, 1922).

La Yupana de Guamán Poma de Ayala

The yupana illustrated by Guamán Poma de Ayala, however, has unanimously been regarded as a counting device (whether or not scholars agree to Guamán Poma's knowledge of its functionality). Hugo Pereyra Sánchez attributes this mutual understanding to the context in which the abacus is illustrated: "In the Guamán Poma illustration the board, without a doubt, accompanies and complements the quipu that the accountant and treasurer extends. In light of such precise testimony, it would be arbitrary to place in doubt the fact that the object represented is an instrument of calculation with which operations were made and whose results were recorded on the quipu" (Radicati di Primeglio, 1990, p. 235 my translation). Henry Wassen concurs by denying that the yupana "deals with a game board. . . there is nothing in common between Guaman Poma's drawing and the game boards reproduced by Verneau and Rivet" (Wassén, 1990, p. 214 my translation). This yupana is a 5×4 table etched into the ground or similar flat surface upon which tokens are moved (Guaman Poma specifically indicates that the grain quinoa is used). The

Yupana, Fig. 2 Guaman Poma de Ayala's illustration of the yupana (*bottom left corner*)

columns have distinct numbers of empty (white) and filled (black) spaces (5, 3, 2, and 1), although various scholars, including Pereyra, have proposed that the black tokens are indicative of addition/debits and the white tokens are indicative of subtraction/credits (Fig. 2).

The distinct positional values given to each row and column of the yupana have led to diverse models and interpretations of this abacus. Wassen's initial interpretation (1931) (Fig. 3) has subsequently been disregarded as overly complicated and not one to one (i.e., numbers could be represented by multiple token combinations). Pereyra's model (1990) associates column position value with the etchings on the board (5, 3, 2, and 1) while preserving the decimal progression of the rows (units, tens, hundreds, thousands, ten thousands) (Fig. 4). While this is one way to make sense of the inscribed 5-3-2-1 sequence, this abacus would only require the placement of 1–2 tokens in each box which does not seem congruent with the specific number of

Yupana, Fig. 3 Wassen’s solution (1931). According to this model, Guamán Poma’s yupana would represent the value: $408,257 = 2 \times 1 + 3 \times 5 + 1 \times 30 + 1 \times 10 + 1 \times 50 + 1 \times 150 + 5 \times 100 + 1 \times 1,500 + 1 \times 1,000 + 1 \times 5,000 + 1 \times 30,000 + 2 \times 10,000 + 1 \times 50,000 + 2 \times 150,000$ (Image by author)

Yupana, Fig. 5 Radicati di Primeglio’s version (1979). According to this model, Guamán Poma’s yupana would represent four values: 21,512, 11,013, 20,110, and 1,001 (Image by author)

Yupana, Fig. 4 Pereyra’s proposal (1990). According to this model, Guamán Poma’s yupana would represent the value: $181,826 = 2 \times 5 + 3 \times 5 + 1 \times 1 + 1 \times 50 + 1 \times 30 + 1 \times 20 + 5 \times 500 + 1 \times 200 + 1 \times 5,000 + 1 \times 3,000 + 1 \times 1,000 + 2 \times 50,000 + 1 \times 30,000 + 2 \times 20,000$ (Image by author)

empty spaces illustrated by Guamán Poma. Radicati di Primeglio’s model (1979) gives each column the same multiplicative positional value (x1) and mirrors the way in which quipu cords represented numeric values (Fig. 5); this model

Yupana, Fig. 6 Burn’s method. According to this model, Guamán Poma’s yupana would represent the value: 53,636 or 62,645 (if the top row “memory holes” carried a token of higher place value); the placement of tokens in the top row ultimately indicates that the operation is not yet finalized (Image by author)

would allow for the simultaneous placement of four numbers (one in each column) but would also require surpassing the limit of token positions as illustrated (5, 3, 2, and 1). The Burns model (1981) preserves the same positional values but only represents one number at a time, thus effectively making use of positions 5, 3, and 2, with the 1-hole space an extra “memory” space intended for carrying over vales between the units, tens, hundreds, thousands, and ten thousands positions (Fig. 6). Burns also somewhat

Yupana, Fig. 7 First-grade students from the *Institución Educativa 3043 Ramón Castilla* using the yupana in the classroom under the direction of their instructor Miguel Angel Díaz Sotelo, the coordinator (Peru) of the

Latin-American Network of Ethnomathematics (see <http://www.etnomatematica.org/home/>) (Photos reproduced with his kind permission)

Yupana, Fig. 8 Showing how the abacus, when positioned vertically, corresponds directly with quipus cord values. This image shows how the number 20130 is

displayed on la yupana as well as the first cord of the quipus (Image by author, published in Leonard 2010, p. 92)

arbitrarily rotated the abacus on its side, but this position's correlation with the contemporary practice of writing numbers from left to right (along with the abacus's use of the decimal system) makes this model a popular choice for implementation in elementary schools (Fig. 7).

Performing Operations on the Yupana

The model proposed by the author (Leonard 2010) is a variation of the Burns model and essentially operates in the same way but positions the yupana as illustrated by Guamán Poma in order to preserve correspondence between the

Yupana, Fig. 9 Addition on the yupana (Image by author, published in Leonard 2010, p. 95)

Yupana, Fig. 10 Division simplified by incorporating mental mathematics and factorization (i.e., $7,191/153 = 7,191/(51 \times 3) = (7,191/51)/3$). The long division

illustrated alongside the yupana is intended to serve as a comparison, even though pen and paper are not necessary for performing this operation (Image by author)

yupana and the quipu in which numbers are read from top to bottom (Figs. 8, 9, 10 and 11).

Addition (as executed in Fig. 7) is the most straightforward of all calculations and probably one of the most common operations. One of the

summands is placed on la yupana while the other summand is placed outside la yupana, to the right of the corresponding rows (A). The stones outside the abacus in the ones row are added to la yupana first (B), using the memory stone as needed.

Yupana, Fig. 11 Division on the yupana (Image by author, published in Leonard 2010, p. 102)

Whenever the total number of stones in any given row reaches ten (hence, the 5 square, 3 square, and 2 square are all full), then those stones can be removed and one stone placed in the single hole (the memory hole) on the right (C). The rest of the stones can then be added to the now-empty holes of that same row (D). After all the stones have been added, the stone from the memory hole can be shifted up to occupy a space in the next row up (E), and the process continues by adding the summand from that next row. All the place values

are computed in the same fashion, always moving from the bottom to top. Once all the summand stones on the right side of the abacus have been worked into the calculation, the number remaining on la yupana is the answer, in our case 516.

Subtraction is a similar computation, but the steps are done in reverse. Multiplication and division are also possible using this method but require the use of additional yupana to prepare some partial products needed in the operation.

These operations can be viewed in their entirety in this author's article "The Incan Abacus" on the website of the *Journal of Mathematics and Culture* (volume 5, number 2): <http://nasgem.rpi.edu/pl/journal-mathematics-culture-volume-5-number-2>. Here, an interesting connection between the enigmatic sequence 5-3-2-1, Fibonacci's sequence, partial products, number decomposition, and Aymara linguistics is also established.

Final Reflections and Operation Simplification

Further reflection on the functionality of the yupana, however, questions the need to establish the possibility of performing addition, subtraction, multiplication, and division. Most models have been criticized for the complexity of the multiplication and division operations, but until additional evidence of the exact nature of Inca operations and necessities of calculation is established, it is difficult to know which exact operations would have been carried out on the abacus. In addition, we must accept that those using the abacus would have been highly trained operators, greatly reducing what constitutes complexity to them. Finally, if we consider the possibility of the use of strategic mental mathematics and factorization, these abacus operations can be greatly reduced and as simple as those calculated using pen and paper, as seen by comparing a simplified version of division (Fig. 10) with a Burn's inspired model of division (Fig. 11).

Zacut, Abraham

José Chabás

Abraham bar Samuel bar Abraham Zacut was the most prominent astronomer of the late Middle Ages in the Iberian peninsula. He was born in 1452 in Salamanca (Spain), a Castilian town whose university had established a renowned chair of astrology (including astronomy) in the mid-fifteenth century.

Although he is chiefly known for his astronomical activity, Zacut wrote on other subjects such as lexicography (*Hosafot lasefer ha-'arukh*) and history (*Sefer Yuhasin*).

Zacut's most outstanding work is *Ha-ḥibbur ha-gadol* (The Great Composition), a text in Hebrew consisting of more than 50 astronomical tables and lengthy canons explaining their use. The tables have 1473 as radix, they are arranged for the Christian calendar, and their entries are computed for the meridian of Salamanca. The tables give the positions of the Sun, the Moon, and the five planets presented in the form of an almanac. Of special interest are the tables listing the daily positions of the Sun (for 4 years from 1473) and the Moon (for 31 years from 1473). All the entries are computed according to the Alfonsine Tables, well known in Salamanca since the arrival of Nicholas Polonius, the incumbent of the chair of astrology at the University of Salamanca ca. 1460. Another table lists all

true syzygies (new and full moons) for 31 years; it is based on the cycle of 767 syzygies discovered by the Catalan astronomer, Jacob ben David Bonjorn, author of astronomical tables for Perpignan (1361), and a follower of ► [Levi ben Gerson](#) (1288–1344). Among others, both these Jewish astronomers are mentioned in Zacut's *ḥibbur*. In fact, the only Christian scholar mentioned in the *ḥibbur* is king Alfonso of Castile. The work was finished around 1478, and 3 years later it was translated from Hebrew to Castilian, with the help of Zacut himself, by Juan de Salaya, who held the chair of astrology after Nicholas Polonius.

At the request of his new patron, Juan de Zúñiga, Master of the Order of Alcántara, in 1486 Zacut wrote a book on medical astrology: *Tratado de las influencias del cielo* (*Treatise on the Influence of the Heavens*), followed by a short text on eclipses: *Juicio de los eclipses* (Judgment on Eclipses). Two other works on astrology have been attributed to Zacut: *'Oṣar ḥayyim* (Treasure of Life) and *Mishpetei ha-'išṭagnin* (Judgment of the Astrologer).

Because of the expulsion of the Jews decreed by the rulers of Spain (1492), Zacut moved to Portugal and entered the service of King João II as an astronomer and chronicler.

A version of Zacut's *ḥibbur* was published in Leiria, Portugal, under the title *Tabulae tabularum coelestium motuum sive Almanach Perpetuum* (1496). The Portuguese scholar, José Vizinho, was responsible for this version, which

contains a summary of the canons of *Ha-hibbur* and most of its tables. Actually, two editions came out of the Portuguese printing house that year: one with the canons in Castilian, the translation of which was made by Vizinho, the other in Latin. The *Almanach Perpetuum* is said to have played a significant role in the navigation projects of the kingdom of Portugal, and especially the tables giving the daily positions and declinations of the Sun. For a facsimile of the tables, see <http://www.fondoantiguo.us.es/obras/200/index.html>.

After the practice of Judaism was declared illegal in Portugal in 1496, Zacut traveled to Northern Africa and settled in Tunis. He adapted his tables for the year 1501 and he compiled another set of tables, beginning with year 1513, arranged for the Jewish calendar and the meridian of Jerusalem where he then lived. Both sets of tables only survive in fragmentary texts. Zacut died in 1515, probably in Damascus.

Zacut's work had a considerable impact on the astronomical community. All, or some of, the tables in the *Almanach Perpetuum* were reprinted several times in astronomical texts published in 1498, 1502, 1525, and 1528. All four editions were printed in Venice, in three different printing houses. Further evidence for the fame of Zacut and his tables is found in many authors in the late fifteenth and sixteenth centuries, and even later, among Jewish, Muslim, and Christian scholars.

Zanzibar Stone Town

Shinuna Karume-Robert
London School of Economics, Yaoundé,
Cameroon, UK

Zanzibar, part of Tanzania, is an archipelago of two main islands, Unguja and Pemba off the coast of Africa in the Indian Ocean. The Stone Town, the old town and historical capital, has an estimated population of 30,000 people. The tropical climate, fertile soils, plentiful waters, and ready supply of building materials offered all that was required for early urban development (Siravo & Bianca, 1996). Zanzibar, strategically located merely 40km from mainland Africa coupled with regular monsoon winds, presented ideal circumstances for seaborne trading and commerce activities between merchants from Asia, primarily India and the Arab peninsula, and Africa. These circumstances also presented a perfect opportunity for a cosmopolitan and culturally diverse town to flourish.

The well-preserved stone buildings and the thriving dynamic Swahili culture have rendered Zanzibar Stone Town as one of the best manifestations of trade and maritime history on the East African Coast. Zanzibar Town is also famous for the important role it played on one hand to advance the slave trade and on the other hand to promote antislavery campaigns led by important personalities such as David Livingstone at the end of the nineteenth century.

Before the arrival of the European and Asian merchants and explorers, the island of Zanzibar only had a series of small harbors and fishing towns developed under the influence from the interior of Africa and from islands across the

Indian Ocean. Consequently, a confederation of small coastal city states known as the Zenj bar (Black Empire), which operated between the eighth and tenth centuries, grew in importance. The best preserved of these towns is Zanzibar, the name of which is derived from the Persian-Arabic word meaning “the coast of the blacks.”

With the arrival of the Portuguese in the sixteenth century, Zanzibar saw the introduction and growth of the slave trade with demand driven by the Arabs in their interest to sustain their plantation economy in the Coast of East Africa and by the French islands in the Indian Ocean. Still standing to this day is the Portuguese-constructed Old Fort on the seafront. It is a testimony to the Portuguese indirect control of Zanzibar and their interest in controlling maritime activities and particularly trading in the Indian Ocean. In 1698, Zanzibar thereafter fell under the Arab control when the Sultanate of Oman took over control from the Portuguese (Sheriff 1995a). It was only in 1840 during the reign of Sultan Seyyid Said that the Stone Town expanded to take the shape known today, set off by the Sultan’s decision to officially relocate his capital from Oman to Zanzibar.

With growing and expanding trade, particularly clove and slave trade, attaining its climax in the middle of the nineteenth century, Zanzibar Stone Town prospered under the ruling Arab Sultans and its foreign merchants from Asia and inside Africa. Under the reign of Sultan Barghash (1870–1888), the House of Wonders, a prominent landmark, was constructed along with the provision of piped water and electricity, thereafter transforming the town into a modern urban city. These developments provided an impetus of spontaneous construction of palaces and houses for the rich Arabs, simple in their architectural integrity but grand and extravagant in space and finishing, with high ceilings, huge windows from airy large rooms overlooking the Indian Ocean, and intricate and elegant large Arab doors. Amidst the predominant Arab stone architecture, Indian traders and artisanal professionals also enjoyed the prospects of extending their traditions in building multistory houses with intricate verandas, a reminiscent of the Gujarati havelis.

As the predominant Arab mortared coral and flat roof architecture became the main feature of the town, it became known as the Stone Town and was thereafter referred to along the East African Coast as the Stone Town of Zanzibar. This name symbolizes the reputation and magnificence of stone architecture along the African coast where most houses were predominately constructed with mud and thatched roofs.

In 1890 when Zanzibar became a British protectorate, the town saw the introduction of the British architectural influence. Under the influence of the architect John Sinclair, the British colonial architecture in Zanzibar was strongly influenced by Islamic architecture from Istanbul and Morocco, perfectly fitting harmoniously with Arabic fabrics. With the strong presence of the British, European missionary activities also prospered, resulting in the construction of the Anglican and Roman Catholic Cathedral.

In January 1964, shortly after the Arab Sultanate gained independence from the British, an African-led revolution overthrew the Arab Oman Sultanate, based on minority rule, ushering in a predominantly African government. The same year in April, Zanzibar made the then strategic move to unite with Tanganyika to form the United Republic of Tanzania. The new government neglected the old town, fortunately without destroying the buildings, regarded as a symbol of their oppressors.

Over two decades of abandonment, the Stone Town was left in a state of deterioration, and only in the early 1990s, when Zanzibar opened its doors to tourism, was the importance of preserving its cultural heritage recognized. With this development, Zanzibar saw the establishment of the Stone Town Conservation and Development Authority (STCDA), a government institution established primarily to assume responsibility for the reconstruction and sustainable conservation of the old town with full legal authority to empower its implementation capacity.

Today, Zanzibar Stone Town continues to boast its rich history of the Indian Ocean trade activity and its important role in the suppression of slave activities and interaction with the rich civilizations from Africa, Asia, and Europe.

It illustrates an outstanding architectural and cultural manifestation of fusion and harmonization. In 2000, Zanzibar Stone Town was officially named a UNESCO World Heritage site, under criteria II–III and VI (1):

(1) World Heritage in Africa – ICOMOS Documentation Center

Criterion ii: The Stone Town of Zanzibar is an outstanding material manifestation of cultural fusion and harmonization.

Criterion iii: For many centuries there was intense seaborne trading activity between Asia and Africa, and this is illustrated in an exceptional manner by the architecture and urban structure of the Stone Town.

Criterion vi: Zanzibar has great symbolic importance in the suppression of slavery, since it was one of the main slave-trading ports in East Africa and also the base from which its opponents such as David Livingstone conducted their campaign.

Zero

R. N. Mukherjee

Mathematics today owes its existence in part to the discovery of zero. For the purpose of calculation it needed a short symbol, which is at present denoted by a small circle in nearly every part of

the world. In India in the early period the form of short symbol which represented zero (*śūnya*) was both a dot and a small circle.

In the Vedic literature, in the *Amarakosa*, zero (*śūnyam bindau*) was represented by a dot. The form was also suggested by the word *kṣudra* (very small) in the *Atharvaveda*. The word *randhra*, used in the Hindu *Gaṇita Sastraka*, indicated a small hole. There are many examples of zero being represented as a dot in the Kashmirian *Atharvaveda*, both in the marginal notes and in the text itself.

In the marginal notes, the numbers are as follows:

Symbol	Number	Folio	Page
◇••	100	100b	192
◇•◇	101	101b	194
◇2•	170	170b	310

The symbols in the marginal notes represented the Folio numbers. In most of the pages of the book there are examples of the above type. In the text itself the following numbers are found:

Small circles in pairs have been used to denote blank spaces in the text. In Folio No. 178a, page 323 in the last line, pairs of small circles are found as follows:

The numbers in the marginal notes may be taken from a later period, but the symbols in the text itself must be from the time of the *Atharvaveda* (500 BCE).

In the Bakhshālī Manuscript, the oldest extant manuscript in Indian mathematics (AD 200), the symbol  represents the number 4,000, while the symbol  represents 500,000,000. The fourth zero in the manuscript is a small circle; the others are dots. In the Shahpur Stone image Inscription of Aditya Sena Bihar, India (AD 672), the symbol  stands for 60, and zero is represented as a dot. In the Malay Inscription at Katakapur (AD 686), symbol  represents the number 608 (*Śāka*), and zero is represented as a circle with a deep circumference.

In the above examples it is found that zero has been exhibited either as a dot or as a small circle to fit in numbers in the place value scale, or to represent absence. In the inscriptions at Sambor, Palembang, and Kotakapur, which were Indian colonies of the Far East, the numbers have been written to represent the Śāka era. Hence undoubtedly they also represent an Indian origin.

Now the question arises as to why zero has been represented as dot or a small circle and not as a square or rectangle or anything else. Two reasons can be assigned: one is spiritual or metaphysical, the other is physical or atomic.

In the spiritual sphere, *śūnya*, or zero or nothing, the symbol of absence of everything, identifies itself with *Nirguṇa* Brahma, the absence of all qualities. The no-quality (*Nirguṇa*) in Brahma represents the fact that He is not guided by any of the qualities or constituents of nature. But at the same time Brahma is the source of all qualities, energy, power, and strength. Similarly *śūnya* or zero itself signifies absence when placed independently, but it represents fullness when it is placed in the decimal system of numeration. (Placing zeros on the right side of a number increases the value to an infinite step.)

Since the conception of *śūnya* identifies with the conception of Brahma both in absence and fullness, the symbol of *śūnya* (zero) must be guided by the symbol of Brahma. The conception of Brahma lies in meditation on a particular point or small circle in the space between the two eyebrows.

Swami Sivananda has given concentration the name “one-pointedness”. Concentration can also start by fixing one’s gaze on a black dot on the wall and later on a bright light first of the size of a pinpoint and later of the size of a sun coming out from the space in between the two eyebrows. Hence the symbol of Brahma can be taken to be a dot or a small circle, and therefore the symbol of mathematical zero is either a point or a small circle.

There are also physical reasons for the symbol for zero. Planets seen from the earth look just like dots. From Vedic times Indians excelled in astronomical observations as we can see in the *Vedāṅga Jyotiṣa* (1200 BCE). So the physical reason for zeros being represented as a dot or a

small circle lies in the fact that the sun, moon, and planets were seen as dots or small circles to an observer on the earth.

Now why should a planet be chosen to represent zero? It is because of the other interpretation of mathematical zero, the absence of atoms. The idea of the atom was mentioned in ancient times in the Buddhist work *Lalita Vistara* (500 BCE). The nucleus of the atom is so small that it is a *kṣudra* (minute), a synonym for zero in the *Athravaveda*. Thus the absence in mathematical zero is guided by the absence inherent in the smallness of an atom or its nucleus. The concept of the fullness of mathematical zero is also present in the infinite motion of the planets and of the electrons around the nucleus of an atom.

The electron has no mass in the material sense, and the mass which it has developed from electrical energy is negligible. This guides the concept of mathematical zero. The movement of electrons around the nucleus with a very high velocity and in an infinite motion is identical with the concept of fullness of mathematical zero which guides the numbers to move in an infinite journey like 10, 100, 1000, 10,000 to 10^n .

Thus the double interpretations, absence and fullness, of mathematical zero are identical with the double interpretations in a planet, and the symbol of zero is guided by the symbol of a planet which is observed either as a dot or a small circle and whose path is almost circular.

Zero has a double meaning in Vedic literature. Etymologically the word *śūnya* comes from the word *śūna* (*śūna* + *yat*). The word *śūna* has two meanings. One is the killing of animals or the slaughter house, which represents absence; the other is increase, which leads to the conception of fullness.

The synonyms of zero, *randhra*, *tuccha*, *kṣudra*, and *ritka* project a concept of nothingness, while the synonyms *vyoma*, *diba*, *akasa*, *antariksa*, and *jaladhra patha* mean infinite expanse of sky. *Purna* means full, and *ananta* means infinite. *Drabinam* and *balam* mean strength, vigor, and force.

Zero, though it signifies nothing, has a full voltage battery charge when used in the decimal place value system.

To understand how the West came to the peculiar conclusion that mathematics is metaphysics, we need to go back all the way to Plato. In Plato's story of Socrates and the slave boy, Socrates first elicits the boy's innate knowledge of mathematics and then declares that he has proved the existence of the soul! (His argument is that since the slave boy did not learn mathematics in this life, his innate knowledge of mathematics proves that he learnt it in a previous life.) Indeed, "mathematics" derives from *mathesis*. Though *mathesis* just means "learning," Plato had a special understanding of "learning," and stated that "all learning is recollection" – of the knowledge the soul had acquired in its previous lives but has forgotten since its birth. This belief in the previous lives of the soul was based on the belief in quasi-cyclic time. (See article on "► [Time](#)".) With a quasi-recurrent cosmos, rebirth takes place in successive cycles of the cosmos. Not only are humans reborn, but all events repeat approximately, so it is indeed natural to suppose that memories too commence afresh. *Mathesis* then becomes a mysterious way to arouse and bring back those lost memories of previous lives in a previous cycle of the cosmos. Proclus (1970) believed that mathematics (and not geography, for instance contains eternal truths and is best suited to arouse the eternal soul.)

This notion of the soul and its previous lives ran afoul of the church, which cursed it in the sixth century, when it also banned mathematics and philosophy from Christendom (Raju, 2003). The Western understanding of mathematics changed further in the twelfth century, during the Crusades, when the church accepted back mathematics, but reinterpreted it as concerned not with arousing the soul but with rational persuasion or metaphysical proofs. Nonetheless, the belief that mathematics contains eternal truths lingered on. Indeed, Aquinas claimed that God ruled the world with eternal laws of nature, and it came to be believed that those laws were hence written in the language of mathematics (since mathematics was believed to contain eternal truths).

This belief in eternal truths led to the related belief in the "perfection" of mathematics; any imperfection was bound to be exposed during eternity! As Berkeley (1734) put it "It is said,

that the minutest Errors are not to be neglected in Mathematics." The belief in perfection led to the rejection of the empirical in Western mathematics. Indeed, Plato deprecated the empirical world as inferior, and Westerners came to believe that this perfection of mathematics could only be achieved through metaphysics, which gave a higher form of truth than empirical truth. It is still believed, on Tarski-Wittgenstein semantics, that empirical truths are contingent truths (true in some possible worlds), weaker than mathematical truths, which are necessary truths (true in all possible worlds), relative to the axioms. Consequently, the present-day philosophy of formalism still supposes that mathematics (being a higher form of truth) must be 100 % metaphysics. The number 2 is today defined solely with reference to Peano's axioms and *not* ostensibly by pointing to 2 oranges, 2 dogs, etc.

All these beliefs are in sharp contrast to zeroism. To begin with, how do we know that there are any eternal truths? Like science, zeroism admits only two means of knowledge: *pratyakṣa* or the empirically manifest and *anumāna* or inference. Totally contrary to the belief in eternal truths, it is manifest that nothing persists unchanged for even two instants. This is often wrongly called the Buddhist doctrine of flux. It is, however, not a doctrine but a simple observation, repeated thousands of times each day. Those who claim the existence of something (such as the soul) which stays constant and unchanged across time need to prove its existence. This has never been done. Thus, this *śūnyavāda* denial of the soul (*anātmavāda*) is fundamentally different from the church curse on "cyclic" time which sought to dictate the nature of the physical cosmos on doctrinaire and political grounds. All that is denied in *śūnyavāda* is the continuation of an unchanged identity from one instant to the next, and this is done solely on grounds of observation and absence of any proof for the existence of something unchanged.

Denying the continuation of identity may seem counterintuitive since our thinking involves language, and the belief in persistence of identity is part of natural language. Thus, the simple statement "When I was a boy," suggests the

persistence of some unchanging identity, the “I” which applies to both me and the boy. This clearly neglects the manifest differences, such as my gray hair or reduced physical activity, compared to the boy. On *śūnyavāda*, I and the boy are really two distinct individuals with some memories in common. For practical purposes, we may neglect the difference as somehow “small.” Zeroism accepts this practical process of neglecting or zeroing things regarded as unimportant in the context, on the grounds of the paucity of names: it would be cumbersome to speak of Ashok1, Ashok2, Ashok3, etc., with one Ashok for each instance. Treating slightly different multiple entities, as if they were one, is a necessity, because on realistic zeroism, or *śūnyavāda*, there is no valid basis for the idealistic doctrine of eternal (or persistent) entities or truths, which doctrine is rejected as erroneous. This corresponds to the exact antithesis of the formalist doctrine that only metaphysics gives “perfect” mathematics and that all practical representations (which ignore minute differences) are erroneous.

Let us illustrate this with an elementary mathematical example. Consider the iterative procedure to calculate square roots, the earliest record of which comes to us from Āryabhaṭa (Aryabhatīya, Ganita, 4, 1976). If we try to extract the square root of 2, this algorithm will not terminate. If it terminates, that will give us a finite decimal expansion or a fraction, formally called a rational number, and $\sqrt{2}$ cannot be represented by a fraction. The pattern of digits in the infinite decimal expansion for $\sqrt{2}$ will not recur either, for a recurrent decimal expansion too corresponds to a fraction by the formula for the sum of an infinite geometric series (see “► [Calculus](#)”).

This (nonterminating, nonrecurrent) decimal expansion corresponds to an infinite sum: $\sqrt{2} = 1.414\ldots = 1 + \frac{4}{10} + \frac{1}{100} + \frac{4}{1000} + \ldots$. Carrying out the infinite sum by physically adding successive terms is impossible, a supertask (or an infinite task which will take an eternity of time). Therefore, the universal practical procedure is to stop at the level of accuracy needed

for the practical application at hand and neglect or zero the remaining digits as unimportant to the practical context. For example, $\sqrt{2} = 1.414$. Or, for example, a calculator might give $\sqrt{2} = 1.4142135623730950488016887242097$ and zero the remaining digits. The exact number of decimal places after which we stop is not important. The point is we have no option but to stop, after a finite number of steps, no matter how large.

This universal procedure is good for any practical application of mathematics. Indeed, a practical task must be accomplished in a limited period of time; therefore, for practical application of mathematics, this is the only procedure available. Since each zeroed digit is at most 9, we can easily estimate the maximum possible inaccuracy by using the formula for the infinite geometric series (which formula too involves zeroing the insignificant). We can improve the accuracy to any desired level, but can never achieve perfection; contrary to Berkeley, some “minute error” would have to be neglected.

However, in search of “perfection,” formalism today insists that the only correct procedure is to sum the entire infinite series. Since that cannot be done physically, it is done metaphysically. Since the sum cannot be a fraction, it is assigned a meaning through a special metaphysics of infinity which is used to construct a number system misleadingly called the “real” number system. In fact, the usual construction of this number system requires set theory which brings in further metaphysics of infinity. Unlike practical procedures, this metaphysics is not universal, but the universal practical procedures are declared as “erroneous.” For example, most practical calculations today involve the use of computers which cannot handle the Western metaphysics of infinity implicit in formal “real numbers,” and computers use a different arithmetic (of floating point numbers) which is declared erroneous.

Indeed, on zeroism, this “discarding of insignificant quantities” is not an error; it involves a fundamentally different understanding of mathematics, not as eternal truth, not as something perfect, but as concerning practical calculations. This was the understanding with which

mathematics developed in India since the days of the *śulba sūtra*-s, through Āryabhaṭa down to the 15th c. Nīlakantha. Thus, *śulba sūtra*-s used the term *sa-viśeṣa* (with something left out) (Baudhāyana, *śulba sūtra*, 2.12, 1983) or *sānitya* (impermanent) (Apastamba *śulba sūtra* 3.2, 1930), while Āryabhaṭa used the term *āsanna* (near value) (Āryabhaṭīya, Gan. ita, 10, 1976), and Nīlakantha explained why the “real value” cannot be given. There was never any religious doctrine of mathematics as eternal truth nor its corollary that mathematics must be perfect and that this perfection can only be attained through a particular metaphysics of infinity. On zeroism, the representation $\sqrt{2}$ is acceptable only due to a paucity of names and functions exactly like the single name “Ashok” which refers to a multiplicity of slightly different entities, 1.4, 1.41, 1.414, etc.

Though we have taken $\sqrt{2}$ as an example, the practical use of numbers is inevitably tied to neglecting or zeroing of some tiny differences. Thus, when we speak of two oranges, we neglect as unimportant the fact that no two oranges are identical any more than any two persons are identical. What we mean is that the differences between the two oranges are irrelevant to the context. Hence, even the attempt to understand integers formally, through Peano’s axioms, involves the metaphysics of infinity in a subtle way. This is clear from the fact that computers can never do supposedly “perfect” Peano arithmetic. [For ints on a computer, see C. K. Raju (2001). A more detailed account of why this happens can be found in <http://ckraju.net/hps2-aiu/ints.pdf>.]

This contrast between the two different philosophies of mathematics, the religious and the practical, created enormous difficulties in understanding the infinite series of the Indian calculus when it was first imported into Europe, and Europeans conflated the two distinct streams of mathematics and tried to understand the practical in religious terms.

Thus, Descartes (1996) went so far as to declare that the ratios of curved and straight lines were beyond the capacity of the human

mind! A charitable interpretation of his statement is that he was alluding to the ratio of the circumference to the diameter of a circle. That is a number today called π and represented by the infinite series $\pi = 3.1415 \dots$, and especially the series today is wrongly called the Leibniz series. Descartes thought this involved an infinite sum or a supertask which was beyond the human mind. In fact, this comparison is very easily done using a flexible string to measure the length of the curved line and then straightening it to measure the straight line. This was how it was taught to children in India, since the days of the *śulba sūtra* (*śulba* means string), and can still be taught in preference to the ritualistic compass box which has no instrument to measure curved lines (Raju, 2009).

Of course, even on this charitable interpretation, Descartes was completely wrong in imagining that the issue specifically concerned curved lines. Thus, exactly the same problem arises with $\sqrt{2}$, which corresponds to the diagonal of a unit square: hence concerns a ratio only of two straight lines. The real issue is zeroism versus idealism. Historically speaking, however, Western mathematicians accepted Descartes’ objections, and Newton thought he had resolved them and made calculus “perfect” by making time metaphysical (Raju, 2006, 2012). Ironically, Newton’s physics failed for the very reason that he made the conceptual mistake of making time metaphysical (Raju, 1994).

This historical legacy of Western problems with the perfect way to understand infinity/eternity persists to this day in calculus as taught in schools and colleges today. Though Newton’s fluxions have been abandoned, all university calculus texts state the belief that metaphysical, formal “real” numbers are essential for the calculus. This belief is false (Raju, 2012). Indian calculus developed with a different number system (“unexpressed fractions,” formally the field of rational functions, a field larger than formal real numbers, which is hence “non-Archimedean”) in which limits are not unique, and, formally speaking, infinitesimals must be discarded (see article on Calculus). Today, differential equations are

numerically solved on a computer using a smaller number system of floating point numbers, and this too involves discarding or zeroing small numbers regarded as insignificant for the practical purpose at hand.

In the practical application of calculus to physics, there are many current problems with infinity, such as the renormalization problem of quantum field theory (Raju, 1983), the runaway solutions of Maxwellian electrodynamics (Raju and Raju, 2011), or the problem of differentiating discontinuous functions, as in shock waves in general relativity (Raju, 2007). These problems all arise just because the Indian calculus was not properly understood in Europe, just because of the belief in the perfection of mathematics which led to the metaphysics of infinity on which present-day formalism is based. More fundamentally, for example, the metaphysics of infinity in present-day mathematics is incorporated into (formal) set theory. Though many of the earlier problems (such as Russell's paradox or problems with transfinite induction) are deemed to have been resolved, we still have, for example, the Banach-Tarski paradox which provides us with a source of unlimited wealth: it says that a ball of gold can be cut into a finite number of pieces which can then be reassembled into two balls of gold each identical to the original one! The huge metaphysical structure of set theory needed even to define simple numbers such as 2 creates enormous learning difficulties in mathematics. Zeroism is of contemporary importance since it helps to resolve both pedagogical and scientific problems.

Western philosophers and mathematicians did not notice a key problem with their beliefs. On the one hand, they believed mathematics was universal, and on the other hand, they believed perfection could only be found in metaphysics. They neglected to ask: which metaphysics? Unlike the universal procedure of practical calculation, Western metaphysics is no obviously universal. For example, empirical proofs are universally accepted by all Indian systems of philosophy, without any exception. They all accept the *pratyakṣa* or the empirically manifest as a valid means of knowledge or proof as does Islam (*tajurba*) and science (experiment). Further,

empirical proofs are the only means of proof accepted by all Indian systems, since the Lokayata (or common people's philosophy) rejects *anumāna* (inference or deduction) as unreliable (and Buddhists reject as unreliable any means of proof other than *pratyakṣa* and *anumāna*). Thus, the elevation of metaphysical proofs above empirical proofs is a cultural idiosyncrasy of the West which is decidedly not universal, and its use in the philosophy of mathematics makes that Western mathematics nonuniversal. (It is another matter that the colonial education process makes Western mathematics normatively universal.)

Further, Western thought has dogmatically maintained, since the Crusades, that inference (or deduction) is the only reliable means of proof. Now, inference or reasoning is based on logic, and the West naively assumed that "reason" (meaning two-valued logic) is universal. This belief in the universality of "Aristotelian" logic was tied to the dogmas of the Christian rational theology of Aquinas and schoolmen, which developed during the Crusades, and maintained that even God was bound by logic in the sense that he could not create an illogical world. Since they, however, believed that God was free to create facts of his choice (while creating the world), therefore they thought that logical proofs are stronger than (or superior to) empirical proofs (since God is bound by logic, but not by facts). This belief is reflected in Tarski-Wittgenstein semantic of possible worlds: in contrast to facts which are contingent truths (true in some possible worlds), mathematical theorems are believed to be necessary truths (true in all possible worlds). The only difference is that instead of possible worlds which God could create, one speaks of possible logical worlds in the sense of Wittgenstein. In actual fact, there is nothing divine or unique about logic except in the Western imagination; there are an infinity of logics to choose from.

Logic is not even culturally unique (e.g., Buddhist *catuṣkoṭi* or Jain *syādvāda* are not 2-valued or even truth functional) (See article on Logic). Accordingly, if logic is decided on cultural grounds, then that obviously involves a cultural

bias. If, on the other hand, logic itself is determined empirically, from facts, logical proofs cannot be stronger than (or superior to) empirical proofs, i.e., in principle. (In practice, of course, deductive proofs are far more fallible than empirical proofs, as is clear from the most elementary first proposition of the *Elements*, which uses an empirical proof, but this was not noticed for 700 years (Raju, 2012), during which it was regarded as a model of deductive proofs.) Changing logic would naturally change the theorems that can formally be deduced from a given set of axioms. Therefore, contrary to the Western belief, mathematical theorems are not necessary truths relative to axioms but are at best truths relative to both axioms and logic.

To summarize, zeroism denies the existence of persistent truths and, consequently, treats the belief in eternal truths as an error. The West, because of its earlier belief that mathematics contains eternal truths, believed that mathematics must be perfect, and this perfection could be achieved only through metaphysics, especially the metaphysics of infinity (closely related to the theology of eternity). However, Western metaphysics is not universal as has falsely been claimed. For example, all Indian schools of philosophy accept empirical proof as applicable to mathematics and superior to metaphysical proof. Further, even logic is not universal, as has wrongly been claimed in the West, since Buddhist logic and Jain logic are fundamentally different from the two-valued logic declared universal in the West. (The Western belief in the universality of logic is based on the theological argument that logic supposedly binds the Christian God and is hence universal.) Choosing logic on cultural grounds would naturally result in a cultural bias, but choosing it on empirical grounds means the belief that metaphysical proofs are stronger than empirical proofs must be abandoned. (Also, as quantum logic shows, two-valued logic is still not the automatic choice.) In either case, there is no basis left for formalism.

Zeroism is ideally suited to the practical applications of mathematics. Indeed, zeroism enhances the practical reach of mathematics, since there are many situations where calculations are possible, but metaphysical proof is not:

for example, stochastic differential equations driven by Levy motion, where solutions can be calculated but cannot be formally proven to exist (Raju, 2001). The advantages of zeroism are particularly evident in physics where the classical calculus with limits fails as does its extension, the Schwartz theory of distributions. Limits also fail in statistics, for relative frequency converges to probability only in a probabilistic sense (Raju, 2011). Zeroism works very well in this situation.

The use of zeroism has the further advantage that it greatly simplifies mathematics in situations such as the calculus. The derivative no longer represents the slope of the tangent (the best linear approximation to a curve) but only the slope of a chord (a good linear approximation to the curve). As usual, one name serves to represent a multiplicity of slightly different entities, the differences being irrelevant for practical applications. All that is given up is the oxymoronic demand for the “best approximation.” This not only suits computational mathematics, it simplifies pedagogy. Making math easy means that students can tackle much harder problems.

Zhang Heng

Jiang Xiaoyuan

Zhang Heng was a Chinese astronomer, writer, and machinist (AD 78–139). As a man of noble descent, he assumed many official positions, and from AD 115, twice was the head of the imperial astronomical organization for a total of 15 years. He was a versatile man who contributed greatly to Chinese astronomy.

The title of one of his works is *Ling Xian* (Mystical Laws); it is very possibly an outline of astronomy-astrology, but only part of the beginning has been handed down. He made an astronomical instrument like a planetarium to demonstrate the motion of the sun, moon, and planets with stars in the background, and to give the correct time. According to historical records he provided this instrument with an automatic mechanical installation, but the detailed information has not been preserved.

Zhang Heng made a wonderful invention for earthquake measurement. In AD 132 he invented a seismoscope called *Hou Feng Di Dong Yi* (Instrument for Earthquake), and at Luoyang (the capital of the empire) he successfully determined that an earthquake had occurred at a place in the northwest of China more than a thousand kilometers from the capital. We have the following information about this seismograph.

This instrument was cast in copper. Its main body is a standing egg-shaped shell with an erect pendulum in the center. It links eight dragons each of whom, with some dexterous mechanical installations, keeps a small copper ball in its mouth. When an earthquake happens somewhere, the dragon in that direction spits out its ball, so that people know where the earthquake has occurred.

This famous seismoscope was not preserved, so scholars have tried to reproduce it since the nineteenth century. Many reconstructive schemes on the basis of modern seismological principles have been published. Up to now, the most successful was by Wang Zhenduo (1963) of which a model has been made.

Zhang Heng is also an important writer. His *Si Chou Shi* (Four Chapters of Distressed Poems) and *Gui Tian Fu* (To Live in Seclusion) are literary masterpieces and his *Tong Shen G* (Song of Love) is one of the most important early documents for the history of Chinese sexual culture.

Zhang Ji (Zhang Zhongjing)

Fabrizio Pregadio

The Chinese physician and medical author Zhang Ji (ca. 150–220), also known as Zhang Zhongjing, was born in the Nanyang commandery (in modern Henan). As stated in the preface to his main work, he was prompted to study medicine and collect prescriptions by the spread of epidemic diseases which caused the death of several members of his own clan. The preface adds that he was Governor (*taishou*) of Changsha (modern Hunan), but this detail is not independently confirmed by other sources.

Zhang Ji's main work, completed in the first or second decade of the second century, was originally entitled *Shanghan zabīng lun* (Treatise on Cold Damage and Miscellaneous Disorders) and included 16 chapters. The rather intricate bibliographic history of the text cast doubts on its authenticity. About one century after its compilation, Wang Shuhe (ca. 265–317) produced a revised, expanded version. The final six chapters, lost by the Song period, were replaced on the basis of an abridged version, and published as a separate work. The two main parts in which the text is extant today are entitled ► [Shanghan lun](#) (Treatise on Cold Damage) and *Jingui yaoliè* (Essentials from the Golden Casket), respectively. The latter is based on the “Miscellaneous Disorders” section of the original text.

The *Shanghan lun* is the first Chinese medical text devoted to a specific etiology. It is concerned with a class of diseases symptomatized by acute fevers, and named “Cold Damage” after one of their factors. Their diagnosis is based on the

identification of symptoms (*zheng* or “evidence”) that indicate the stage reached by the disease in its progression toward the vital centers of the body. These stages of development are defined according the Six Warps (*liujing*) system, one of the frameworks used to describe the cyclical flow of energy within the body (others are *qi* and *wuxing*, Five Agents or Phases). The text emphasizes the practical rather than the theoretical aspects of healing. Therapy is based on the administration of medicines (the whole work includes more than 300 prescriptions for specific diseases), and to a lesser extent on acupuncture, ► [moxibustion](#), and other methods such as baths and massages.

Zhang Ji's work gave rise to the second most important tradition within Chinese classical medicine after the one represented by the texts of the “Inner Canon of the Yellow Emperor” corpus (► [Huangdi neijing](#)). Although Zhang refers to this corpus in the preface, even the most basic notions of the Inner Canon – e.g., the Five Agents or Phases, the visceral systems (*zangfu*), and the circulation tracts (*jing*) of acupuncture – are absent from his work. As has been pointed out, this is not necessarily a sign of alternative or competing traditions. An extended commentatorial tradition, in fact, has tried to bring together the respective basic notions. Only recent research has shown the ways and extent to which the general framework of the two works differs.

Zhang Qiuqian Suanjing

Lam Lay Yong

Zhang Qiuqian suanjing (The Mathematical Classic of Zhang Qiuqian) is the only known work of the fifth century mathematician, Zhang Qiuqian. It is one of ten mathematical books known collectively as *Suanjing shishu* (Ten Mathematical Classics). In A.D. 656, when mathematics was included in the official examinations, these ten outstanding works, which covered a period of over a thousand years, were specially selected as textbooks.

Jiuzhang suanshu (Nine Chapters on the Mathematical Art) and ► *Sun Zi suanjing* (The Mathematical Classic of Sun Zi) are two of these texts that precede *Zhang Qiuqian suanjing*. All three works share a large number of common topics. Though *Sun Zi suanjing* was intended as a primer, it now provides significant documentation of the rod numerals and their use in multiplication, division, and other mathematical methods. *Jiuzhang suanshu* is undoubtedly the most important and influential of the early mathematical texts. Both works occupy prominent places in the history of Chinese mathematics with one showing the initial learning stage and

the other manifesting an evolutionary culmination. *Zhang Qiuqian suanjing* demonstrates the continuation of the development of mathematics from here, and provides an important bridge of knowledge on the evolution of traditional mathematics to its apogee in the thirteenth century. It is all the more important as such surviving works are few and far between.

Zhang Qiuqian regarded fractions of primary importance; he mentioned the difficulty of the subject in his preface and provided more complicated problems than those in *Jiuzhang suanshu*. There are only very brief general descriptions of finding the square root and the cube root of a number in *Jiuzhang suanshu* and these are written with the use of technical phrases. It is a relief to scholars to find that examples are employed in *Zhang Qiuqian suanjing* to illustrate the step by step procedures of both methods and also to show how the solution of a nonintegral approximation is obtained.

Zhang Qiuqian continued with the tradition of the development of arithmetic by supplying problems involved with what is known in the west as the Rule of Three and extending to problems concerned with proportions, compound proportions, and proportional parts. Other problems are involved with relative speed, different shaped frustums and granaries, the Rule of False Position, the arithmetical progression, the computation of interests and taxes, similar right-angled triangles, and the quadratic equation. There are a number of problems concerned with the well-known *fang cheng* method, which is the Chinese way of solving a set of simultaneous linear equations. The last problem of the book is the famous problem of a hundred fowls. In this problem, somebody is to buy 100 fowls for 100 monetary units, given that a rooster costs five units, a hen 3, and chicks are sold three for one unit. Even though the answers given in the book are correct, it is not clear how the answers were obtained.

Zhang Qiuqian's lucid style has been a great help to the scholar's understanding of how the ancient mathematicians manipulated the rod numerals to arrive at the answer. The existing edition of the book has three chapters with 92 problems; the last portion of the second

chapter and the beginning of the third chapter are incomplete. The book has been translated into English by Ang Tian Se.

Zhang Qiujiang suanjing has an important place in the world history of mathematics: it is one of those rare books before A.D. 500 that manifests the upward development of mathematics fundamentally due to the notations of the numeral system and the common fraction. The numeral system has a place value notation with ten as base, and the concise notation of the common fraction is the one we still use today.

Zheng He

Sally Church

Zheng He was originally from Kunyang in Yunnan province, in Southwest China. Born around 1371 to a Muslim family, he was surnamed Ma, a common Muslim surname derived from the Chinese transliteration of the name Muhammed.

During the 1380s, the Ming government sent troops to Yunnan on an expedition to pacify the region, expel any remaining Mongol influences, and incorporate it solidly into the newly founded regime. At the age of about 10, Zheng He (then Ma He) was captured by Chinese troops, taken prisoner, and selected to become a eunuch. We know that by 1382, when an inscription was written for his father who had passed away, he was taken into the service of Prince Zhu Di, fourth son of the Ming founder, Emperor Hongwu (Zhu Yuanzhang, r. 1368–1398). There Ma He served Zhu Di in his principality of Yanjing (the region of present-day Beijing). Zhu Di was later to become the third Ming emperor, Yongle (r. 1403–1424).

In his early career, Ma He accompanied Zhu Di on military campaigns against Mongol forces in the Yanjing region. He distinguished himself as a military commander in a campaign against the Mongols outside the Great Wall (1393–1397), and then in the civil war (1399–1402) launched by Zhu Di against Hongwu's successor, Jianwen. This war ended in victory for Zhu Di, who usurped the throne from Jianwen in 1402. For loyal service to him during the civil war, and as a reward for suppressing a rebellion in Yunnan, Zhu Di, then Emperor Yongle, conferred the Chinese surname Zheng on his trusted eunuch. This occurred on New Year's Day in 1404. From then on he was known as Zheng He.

Soon after ascending the throne, Yongle began planning the maritime expeditions which have made Zheng He famous. In some respects they were a continuation of the regular conduct of foreign relations – the sending and receiving of envoys to and from foreign countries, particularly in Southeast Asia – which had occurred during Hongwu's reign (1368–1398) and in previous dynasties. As early as the ninth month of 1402, only 3 months after proclaiming himself Emperor, Yongle sent ambassadors to these countries to announce his accession. We are told that envoys came to China from Calicut and Chola (the Coromandel coast) for the first time in 1403. In the eighth month of that year, Yongle reopened the three maritime supervisorates in Zhejiang, Fujian, and Guangdong that had

operated under Hongwu. Ambassadors came and went, and regular tributary and diplomatic relations proceeded as normal.

In the meantime, there were signs that the emperor had a larger-scale of activity in mind. As early as 1402 he had ordered the construction of ocean-going ships in substantial quantities – first 137 ships, and then 200 in that year alone. A further 188 vessels were to be converted (presumably from ocean-going grain transports) the following year, and 55 more new ships were ordered at the beginning of 1404. Emperor Yongle appointed Zheng He commander of the fleet and on 11 July 1405 issued the order for the first expedition to the “Western Oceans” (Xiyang).

The ultimate purpose of these expeditions is not entirely clear, though there were probably diplomatic, military, and economic motivations. The main reason given in the Ming History (*Ming shi*) – that of finding the deposed emperor Jianwen – was probably not the true purpose. It would not have been necessary to send out a fleet of over a hundred ships and 27,000–28,000 men to search for a single person in the vast oceans of Southeast Asia and beyond, nor does this explain the expeditions’ political, military and diplomatic activities in the regions they visited.

In all there were seven major expeditions, each one taking approximately 2 years from departure to return. The dates of the seven were (1) 1405–1407; (2) 1407–1409; (3) 1409–1411; (4) 1413–1415; (5) 1417–1419; (6) 1421–1422; and (7) 1431–1433. The first three departed quickly in succession, with one leaving in the same year as the previous one returned. After the third, there was a 2-year gap between each. Between the sixth and seventh expeditions a space of 9 years intervened because of the death of Emperor Yongle in 1424. He was succeeded by Emperor Hongxi (r. 1424–1425), who saw the expeditions as unnecessary extravagances and called a halt to them. The final expedition was not launched until the reign of Hongxi’s successor, Emperor Xuande (r. 1425–1435). In addition to the seven major expeditions, there were also branch or side expeditions to such countries as Bengal and Thailand.

Because of the monsoon, which Chinese sailors seem to have understood quite early on, the expeditions followed a regular seasonal pattern in their departure and return. They left the port of Taicang (near present-day Shanghai) in the autumn, and sailed down the coast to the port of Changle in Fujian province. There they waited for the monsoon until December or January, before sailing on to Champa (Xin Zhou, present-day Qui Nhon), Java, Palembang, Melaka (Malacca), and various places on the island of Sumatra, including Samudra-Pasai. After crossing the Bay of Bengal, they reached Ceylon (present-day Sri Lanka), and then proceeded to Quilon, Cochin, and finally Calicut, a major emporium of the Indian Ocean trade network at the time. The first three expeditions did not go beyond this point. The fourth went further, to Hormuz, and the fifth, sixth, and seventh expeditions traveled to the Arabian Peninsula and East Africa. The journeys beyond Calicut were probably undertaken by portions of the fleet.

The main scientific and scholarly issues involved are the dates of the various expeditions and their implications for such issues as speed of travel, the numbers and types of ships that sailed on the voyages, the logistics of carrying out such a major operation, the routes the expeditions followed, and the techniques and instruments that were used for navigation. The equipment used for military purposes is also of interest, although details are scarce. With regard to the dates, there is some disagreement in the sources, but the discovery of two stone inscriptions in the 1930s in two separate locations on the Chinese coast, each corroborating the other on the years of departure and return for the seven major voyages, has settled the matter for the most part, thanks to the careful elucidation of the issue by Duyvendak (1938). The numbers and types of ships on the voyages cannot be known exactly, but it is highly unlikely that they were the size given in the *Ming shi* of 44 *zhang* long and 18 *zhang* wide, equivalent to 447 × 183 ft. Moreover, there are serious practical reasons for thinking that the ships could not have been of that size. They would have been proportionally much too wide. Moreover the

available timber would not have allowed a longitudinal strengthening member to have been made in one continuous length, nor could masts of the height required have been made of a single tree trunk. It has also been estimated that as many as 8,000 men would have been needed for the crew, and there is no evidence for ships carrying more than 500 men on them; more likely there were 200–300 crew members. The “Mao Kun map” (see below) shows conventional ships with only three or four masts, although it has been estimated that a ship of 44 *zhang* in length would need nine masts. There are references to 48, 62, or 63, and 100 ships used on individual voyages, and the initial order for ships to be built in 1403 was for 250. Thus it is difficult to be precise as to the size of the fleet, though there were probably over 100 ships on each expedition. The ships must have been of various sizes for different purposes, including ships for military uses, the transport of supplies, and the transport of personnel. More research needs to be done on the question of logistics, to understand how so many sailors and other specialists (including doctors) were recruited, and how supplies were requisitioned and managed on the voyages. Further study of local histories and gazetteers of the coastal regions around ports such as Taicang and Changle may perhaps shed some further light on this question.

The routes and navigation techniques are perhaps the most rewarding issues for scientific investigation. For this, the most important source is the Mao Kun map, called thus by Mills because it appears in a collection of military preparedness materials (*Wu bei zhi*) compiled by Mao Yuanyi (1597–1661), a grandson of Mao Kun (1512–1601). In Chinese, the map is usually called *Zheng He hanghai tu* (Zheng He’s navigation map). It probably came from Mao Kun’s library of military materials, which he collected because of his interest in naval matters deriving from involvement in the coastal defense of Fujian. Significant work on this map has been done in the West, particularly by Mills (1970) in his book on Ma Huan, who accompanied three of Zheng He’s expeditions and wrote an account, entitled *Yingyai shenglan*, of the places they

visited. It is a strip map in 40 folios arranged from right to left, beginning in Nanjing and ending in Hormuz, also showing the east coast of Africa. It depicts not only the places roughly in their geographical locations along the contours of the coast, but also the routes from place to place, marked by dotted lines, and accompanied by sailing directions along the route markings. The sailing directions are expressed in terms of compass points and distances, with occasional references to navigation techniques, such as the need to take soundings in certain areas to avoid shallow waters. Distances are expressed in lengths of time according to the Chinese system of counting watches, or 2-h periods.

The use of astronomy in navigation is evident in some of the sailing directions, particularly those for the north-south route along the coast of Africa, where latitude is indicated by the height of constellations measured in number of fingers at arms’ length above the horizon. The Arabs also used this technique in seafaring. The work concludes with four “stellar diagrams” giving precise instructions for positioning a ship in relation to certain stars and constellations on two key segments of the route – between Sumatra and Ceylon and between Hormuz and Calicut. This was in order to ensure arrival at the correct destination over long expanses of ocean.

The expeditions provided regular contact and involvement with distant countries over the course of almost 30 years. Through the accounts not only of Ma Huan but also of Fei Xin and Gong Zhen, certain circles in China were exposed to foreign ideas, practices, and customs. Needham (1971) suggested that one of the aims of the expeditions was the “search for rarities of all kinds... gems, minerals, plants, animals, drugs and the like” for the court, and that knowledge of foreign science, particularly medicine, was transmitted to and from China during this time. This contact seems to have led to some exchange of information and technology between China and other cultures and civilizations – the Arabs and Indians for example – and could have led to more if it had not been for the suppression of information about the voyages in China due to internal politics. Fearing an increase in eunuch power,

and citing the extravagant expense of the expeditions, the official Liu Daxia, who later became president of the Ministry of War, discredited the first-hand accounts, calling them “deceitful exaggerations of bizarre things far removed from the testimony of people’s ears and eyes.” He destroyed all the documents in the official archives that concerned the voyages.

A question much discussed by scholars is why these expeditions, which showed such a high level of scientific and technological expertise, as well as energy, curiosity, and interest in other countries, stopped abruptly after 1433. Did China simply turn inward, cast aside her quest for knowledge of “the other,” reject science, technology, and progress, and willingly forfeit a prominent role in international relations, thus sealing her fate in the nineteenth and twentieth centuries? Such a view not only relies too much on hindsight but also seriously underestimates the intelligence of the Chinese people. There was also no amorphous “China” that made such a conscious decision. A handful of people with political power took certain steps for their own short-term reasons. To conclude that China at any point in her history rejected technology and progress simply ignores reality. There were engineers, mathematicians, astronomers, and scientists in many fields during all periods of Chinese history who for practical reasons as well as theoretical interest pursued scientific investigation and activities, sometimes in conjunction with, but more often independently of government policy. Instead, a more likely explanation for the cessation of the maritime expeditions is financial – the expeditions were expensive and there were other demands on the imperial coffers at the time, including not only defense against invaders in the north, but also domestic concerns such as famine relief and dyke repair.

Zheng He’s precise time and place of death is not known for certain. It is now accepted in scholarly circles that he did not die abroad, but returned to China and passed away in Nanjing in approximately 1435. A tomb in Nanjing is now conventionally accepted as his.

Despite the destruction of the documents in the official archives, many sources of information about these voyages still survive. Of prime importance are the three first-hand accounts by Ma Huan, Fei Xin, and Gong Zhen, which are remarkable for their attention to the political, economic, social, and religious conditions of the lands they visited, as well as for their frank observations and open attitudes toward the unfamiliar customs and practices they found. In addition to the Mao Kun Map and the various inscriptions on stone steles, including three in China (the Liujiatjiang, Changle, and Jinghai temple inscriptions) and others in the countries they visited, an itinerary for the seventh voyage also survives, preserved in a work by Zhu Yunming, giving the dates of arrival and departure from each place visited by the main portion of the fleet. From this itinerary it is possible to calculate the length of the various legs of the journey and the speed of travel. In addition there are numerous references in the *Ming Shilu*, or “Veritable Records” of the Ming dynasty, particularly to the exchange of ambassadors to and from China. References occur in many other Chinese historical documents as well. In the 1980s Zheng Hesheng and Zheng Yijun collected voluminous references to the voyages in Chinese historical and other documents and included them in their monumental multi-volume work entitled *Zheng He xia Xiyang ziliao huibian* (A Collection of Resource Material on Zheng He’s Voyages to the Western Oceans), a convenient resource for anyone interested in pursuing research on the expeditions.

In 2002 the British submarine commander (retired) Gavin Menzies, in a popular book entitled *1421*, claimed that the expeditions sailed beyond East Africa to “discover” America and circumnavigate the globe. This theory, though presented as historical fact, remains entirely undocumented. Serious scholars continue to pursue the truth about Zheng He’s voyages, and interest in them is currently at a height because it has now been 600 years since their initial launch.

Zhenjiu Dacheng

Richard Bertschinger

The *Zhenjiu Dacheng* (Great Compendium of Acupuncture and ► [Moxibustion](#)) is a digest of acupuncture and moxibustion writings from the

Han to the Ming dynasties. As such, it forms the greatest comprehensive survey of acupuncture in China ever to be produced during classical times. Much of its greatness is due to its selection of works from the Song and Yuan. It was edited by Yang Jizhou in 1601, as the culmination of his life's work. He was then close on 80-years old and obviously still active.

An early title for the work had been “Secrets of the Dark Inner Mechanism of Acupuncture and Moxibustion for the Preservation of Health.” In this text Yang Jizhou included mainly the traditions of his own family, but later he enlarged the book to include earlier literature, and so changed the title. Generally he selected the best of the old, and reedited it, adding a certain amount of his own material where it suited.

The Grand Compendium comprises some ten volumes, covering all aspects of acupuncture and moxibustion. It also contains an appendix on massage techniques particularly suited for children, entitled *Biaoying Shenshu* (The Divine Art of Protecting Infants), taken from an earlier book which is now lost. The work includes listings of channels and points; many point-formulae for medical conditions, particular systems for choosing points; refined needling techniques such as those developed during the Song, Yuan, and Ming; detailed formulae for calculating the precise time and exact point for treatment; glossaries of point names; and selections from the classics, especially the ► [Huangdi Neijing](#) and its slighter companion the *Nan Jing*. This all constitutes a great wealth of historical material.

Particularly striking are the exquisite verse poems selected for the second volume. These include the “Ode to the Golden Needle,” which focuses on needling techniques, the *Liuzhu Zhiwei Fu* (Ode to Intricacies in the Circulating Flow), which outlines the Law of Midday-Midnight in which the choice of points is determined by the particular hour and day of treatment, and the *Biaoyou Fu* (Ode to the Streamer out of the Dark), the longest and most comprehensive of these poems, which contains an extensive commentary by Yang Jizhou.

A gradual increase in prosperity was spawned by better social conditions during the Ming. These in turn created an interest in the old ideas. Undoubtedly influential on Yang's work were the *Zhenjiu Sunan Yaozhi* (Essentials of Acupuncture and Moxibustion, 1536) and the *Zhenjiu Juying* (Gatherings of Outstanding Acupuncturists, 1546), both issued by Gao Wu during the earlier century. Gao Wu's work was particularly commendable as he made a stand against any superstitions in medicine. Where he was uncertain he would simply state it, without comment. From Gao Wu's work Yang took both an uncluttered approach and a grand overview of the acupuncture tradition. In many places Yang Jizhou pays debt to Gao Wu by copying his selection of classical extracts exactly.

Another great influence was the *Shenying Jing* (Classic of Divine Resonance, 1425) by Chen Hui. From this work Yang Jizhou borrowed his simple and practical approach, cutting great swathes through confusing systems of point selection by adhering strictly to the Divine Resonance's printed lists. This compendium is an invaluable treasure for all acupuncturists and has become well-known abroad as well as in China.

Zhenjiu Jiayijing

Richard Bertschinger

The *Zhenjiu Jiayijing* (The A-Z Canon on Acupuncture and ► [Moxibustion](#)) was written by ► [Huangfu Mi](#) (AD 215–282), during the short-lived Jin Dynasty. Needham dates the book as being finished some time between AD 256 and AD 282.

This is the oldest surviving text devoted exclusively to acupuncture and moxibustion. It was produced after the fall of the Han nation, during a time of violent turmoil and disruption in Chinese society. Huangfu Mi summarized the knowledge of his day concerning acupuncture and moxibustion, and ordered the many texts then current. He drew from both sections of the ► [Huangdi Neijing](#) as well as the *Mingtang Kongxue Zhenjiu Zhiyao* (Therapeutic Essentials of the Acupuncture Points Revealed in the Clear-Lit Hall), of unknown authorship, a book now lost. Huangfu Mi took up medicine in middle age because of his own family's illness and his own arthritis.

This book's most impressive character lies in its systematic outline of the subject (as revealed in the title). The many points are grouped under the various channels to which they belong, with number, name, point location, and tips for finding each. Additionally there are listings of the illnesses, or syndromes, for which each can be used, detailing how deep the needle should be inserted and the number of breaths for which it should be retained in position. Tonification or reducing techniques are also described, as well as angling the needle shaft along or against the direction of energy flow down the channel. In addition, Huangfu mentions the use of moxa, the number of cones for each point being duly recorded. All this had never been so accurately or clearly laid out before.

This book, quite justifiably, has had an enormous influence throughout China and abroad. It became *de rigueur* reading for the Japanese imperial colleges from the seventh century, and found its way to Korea even earlier. Its texts have been the foundation of acupuncture teaching and practice for some 70 generations in the East. As yet, there has been no translation into English.

The book's 128 chapters comprise medical theory, the examination and diagnosis; characteristics and pathology of the channels; a complete catalogue of the points; pulse diagnosis; needling technique; outline of pathology and transmission of disease; types of fevers; pains, swelling, coughing, rheumatism, wasting diseases, and dumbness; eye, nose, and throat problems; woman's and children's illness; and appendices.

Huangfu Mi's approach, in particular, stressed the need for a proper adjustment of the patient's emotions. He knew that physical and environmental factors played a part in illness, that treatment should proceed with great care, and that signs and symptoms should be precisely differentiated. All show a clear and intelligent approach to practice.

Very little has changed in the location and identification of acupuncture points since the publication of this text some 1,800 years ago. For instance, it is mentioned in the preface to the *Essentials of Chinese Acupuncture*, the first acupuncture book produced by the Chinese for a Western audience.

Zhoubi Suanjing

Christopher Cullen

Needham Research Institute, Cambridge, UK

The *Zhoubi suanjing* (frequently also romanized as *Zhoubei suanjing*), is an anonymous Chinese work on astronomy and mathematics. It is a composite work which probably reached its final form in the first century A.D. under the Western Han dynasty.

The contents deal mainly with calendrical astronomy, and the shape and size of heaven and earth according to the ► [gaitian](#) (umbrella [-like] heaven) cosmography. It opens with a brief dialogue between the Duke of Zhou (fl. ca. 1000 B.C.E.) and Shang Gao, an otherwise unknown figure, who explains the use of the try-square *ju* and refers briefly to a round heaven lying above a square earth. In connection with the try-square Shang Gao refers cryptically to the relationship between the sides of a 3-4-5 right triangle. The text then continues with a long and fairly coherent section which may be the original core of the book.

In this section an otherwise unknown Chen Zi discusses the use of a gnomon (a vertical pole) for observing the shadow cast by the noon sun. It is claimed that the shadow of a pole 80 *cun* (inches) long changes by 1 *cun* for every 1,000 *li* (about 400 miles) moved north or south in relation to the point on the earth where the sun is directly overhead. The use of this rule, which does not correspond to actual observation, enables the dimensions of the heavens to be calculated. Most of the rest of the book contains calculations relating to the operation of lunisolar calendrical systems of the *si fen* (quarter [remainder]) type. The text bears an important commentary by Zhao Shuang, probably written ca. A.D. 270–280, and has further annotations by ► [Li Chunfeng](#), who prepared an edition for use in the State College in A.D. 656. The book was first printed under the Song dynasty in A.D. 1084.

France

Virtually nothing is known of the life of this Yuan 元 mathematician, except the little we can learn from the prefaces to his two books, *Suanxue qimeng* 算學啟蒙 (*Introduction to Mathematical Studies*, 1299) and *Siyuan yujian* 四元玉鑒 (*The Jade Mirror of the Four Unknowns*, 1303). The first preface was written by Zhao Cheng and the second one by Mo Ruo 莫若 and Zu Yi 祖乙. From those we can surmise that Zhu came from Yanshan 燕山, near modern Beijing; that he traveled around China for more than 20 years in the last decades of the thirteenth century, after China had been unified under the Mongol rule; and that numerous students came to study with him.

His books attest to the fact that he inherited – from the northern milieu of the Hebei 河北 and Shanxi 山西 provinces which developed the “procedure of the celestial unknown (lit.: origin)” (*Tian yuan shu* 天元術) – how to use polynomial algebra to build an equation with which to solve a problem. This achievement seems to have been unknown in South China and benefited from the potentialities of the counting instrument on which it is based: the surface for computing, on which numbers were represented with counting rods which

could be moved or changed in their values throughout the computations. The earliest book that has come down to us and attests this procedure, though it is probably not the first to have dealt with it, dates from 1248. It is Li Ye 李冶’s (or Li Zhi 李治’s, according to the name chosen for this scholar) *Ceyuan haijing* (測軍海鏡 *Sea Mirror of the Circle Measurements*). Yet Zhu Shijie does not mention this author or any other one. On the basis of extensions to polynomials with two and three indeterminates “that the procedure of the celestial unknown had received previously to him,” according to Zu Yi’s preface, Zhu Shijie developed it to what was to remain an unsurpassed peak in Yuan and Ming China: the use of polynomial algebra with four indeterminates to establish an equation to solve a given problem. As Hoe (1977) has stressed, the language and notations with which Zhu Shijie developed this algebra can, in their conciseness and precision, stand comparison with aspects of modern algebraic symbolism. Still, he notices some ambiguous modes of expression that do not make it entirely independent from the context. This very language might help us to make the historical connections between Zhu Shijie and such previous authors as Li Ye more precise, since as far as topics such as right-angled triangles are concerned, both use the same terminology. On the other hand, as regards the expression of formulas, they present differences even though their languages share the same basic features. For the expression of formulas or algorithms, Li Ye uses a language whose syntax is restricted in such a way that the understanding of a formula is unambiguous, which makes it context-free, in contrast to Zhu Shijie’s (Chemla, 2006).

Moreover, Zhu’s writings demonstrate that he shared bits of knowledge (for instance, finite difference procedures for the summation of series, a topic to whose development he made crucial contributions) with the authors of the calendar *Shoushili* 授時曆 commissioned by the Mongol Court, the foremost being Guo Shoujing 郭守敬.

In addition to this – is it a reflection of his travels in South China? – his books reveal his

interest in algorithms for quick, daily-life computations, or for mercantile and bureaucratic mathematics. In the surviving writings from this period, such topics had mainly been treated by mathematicians from South China, such as Yang Hui 陽輝. At the same time, other topics which developed in South China, such as research connected with the Chinese remainder theorem, seem not to have found their way into his writings. Still, Du Shiran 杜石然 (1966) called attention to the fact that Zhu seems to represent a kind of synthesis of traditions that, for at least decades, had been developing in isolation from each other in North and in South China, though they shared a common basis in the same fundamental characteristics and knowledge, including algorithms to find “the root” of any algebraic equation with positive, negative, or null coefficients.

Zhu Shijie’s books do not seem to have had any impact on the development of mathematics in China; not only we do not find any mention of his name or achievements after their publication, but also the books themselves would eventually be lost, to be found again in China and reprinted only at the beginning of the nineteenth century. This merely reflects the progressive loss of mathematical knowledge from the Song-Yuan period. In contrast to other writings of the same period, his *Introduction to Mathematical Studies* was to influence the development of mathematics in Korea and Japan. It was probably printed in 1433 in Korea, where it became a textbook for studying mathematics, and was eventually recovered thanks to a Korean edition of 1660. Moreover, its introduction to Japan in the second half of the seventeenth century, where it was reprinted and commented upon many times, allowed Japanese mathematicians to reconstruct the procedure of the celestial unknown, by that time forgotten in China, and to improve it until it became a tool in some ways comparable to the algebra developed in Europe during the same period. Horiuchi (1994) studies this aspect of the mathematics developed in Japan with great care and compares it with elements of the contemporary European algebra. Indeed, Japanese mathematicians’ use of

the surface for computing for their computations was probably instrumental in that respect, whereas in China this instrument had fallen into oblivion and was completely replaced by the abacus.

Zij

Raymond Mercier

The term *zīj* is used everywhere in the study of Islamic culture to signify an astronomical handbook. These handbooks consist of a collection of astronomical tables together with such textual material as the reader would need in using the tables. The material is often divided into the following sections:

1. Calendrical conversion
2. Mean motions of the sun, moon, and planets
3. Equations of the sun, moon, and planets
4. Positions of fixed stars
5. Trigonometrical tables (sine, tangent)
6. Spherical astronomy
7. Parallax
8. Eclipses of the sun and moon
9. Geographical coordinates
10. Astrological quantities

The underlying theoretical model of planetary equations was almost invariably Ptolemy's, and to a large extent *zīj*es represent a continuation of the *Handy Tables* of Ptolemy (ca. AD 140). However the earliest Arabic *zīj* is that of ► [al-Khwārizmī](#) (ca. AD 830), which was based on procedures derived from the Indian treatise *Brāhmasphuṭasiddhānta* of ► [Brahmagupta](#) (AD 628). A large number of such works survive intact in Arabic and Persian manuscripts, and many others are known by name only. The most notable modern edition (Nallino, 1907) is that of the *Zīj al-ṣābi'* of al-Battānī' (fl. AD 880). For the long Islamic period the *zīj*es are a vital repository of data, primarily through the constant improvements in the parameters of mean motions

reflecting new observations, and also of improvements in mathematical methods.

In most *zīj*es the textual material was generally restricted to instructions in the use of the tables. Larger astronomical treatises, such as the *Qānūn al-Masūdī* of al-Bīrūnī (ca. AD 1030), included all the material which would be found in a *zīj*, but went further in its detailed treatment of the whole subject.

A number of *zīj*es were translated into Latin and Greek, and initially at least, the term *zīj* was transcribed as *ezich*, *ezeig*, etc. (=al-*zīj*), and ***, respectively. In Latin the term was soon replaced by *tabulae*, while in Greek one finds ***, reminiscent of Ptolemy's *Almagest*.

The term *zīj* is originally Middle Persian, where it means "stretched cord." The sense "astronomical handbook" goes back to the early sixth century when Sanskrit works were introduced into Iran. The name *zīj* may have arisen as a literal translation of the Sanskrit term *tantra* (from *tan* "to stretch") literally "warp, loom," but which is used in the sense of "system" or "text book." The word is singled out by ► [Varāhamihira](#) (ca. 580) as the name of the branch of astronomy which is concerned with planetary calculations. In a Middle Persian tract of the ninth century, the *Epistles of Manuščīhr*, there are references to the *zīg ī hindūg* (Indian Astronomy), and also to a *zīg ī šahrīyārān* (Royal Astronomy), a Sasanid compilation probably of the sixth century, referred to later by Arabic authors as the *Zīj al-Shātroyārān*. The former may be one of the works of Āryabhata (ca. AD 5250), which were referred to as Tantras by an early commentator.

Zinc Production in China

Wenli Zhou

Institute for the History of Natural Sciences,
Chinese Academy of Sciences, Beijing, China

Zinc was one of the important metals in the ancient world, primarily as an essential component of the alloy brass. Brass was usually made by the cementation process, whereby metallic copper, zinc ores, and charcoal were heated in crucibles, and brass was formed directly through the absorption of zinc vapor by the copper, rather than by alloying two liquid metals. This technique was required because of the extreme volatility of metallic zinc (it boils at 907 °C), which means zinc immediately volatilizes when it forms from the ore (around 1,000 °C), and it reoxidizes as soon as it comes in contact with air. Thus complex reduction and

condensation installations, rather than ordinary smelting furnaces, are necessary to produce metallic zinc.

While brass cementation was widespread in ancient times, only India and China produced unalloyed zinc on an industrial scale. Indian zinc production, based on the principle of distillation by descending, first appeared about 1,000 years ago, boomed during the fourteenth to sixteenth centuries, and ceased in the nineteenth century at Zawar, northwest India (Craddock et al. 1998). In contrast, the Chinese zinc smelting process was based on the principle of distillation by ascending, which seems fundamentally different from the Indian one. Chinese zinc was mainly used for making brass coins in the Ming and Qing Dynasties (sixteenth to nineteenth centuries); some was traded via European merchants to the world. Traditional zinc smelting was still in operation in southwest China until the late twentieth century (Xu 1986; Craddock and Zhou 2003).

Since the 1920s, a number of Chinese and British scholars have studied Chinese zinc smelting technology and its history, especially its inception, based on three sources of evidence: historical records, scientific analyses of brass coins, and field surveys of traditional zinc production. Zinc had a number of terms in historical records, such as *lian*连/鑪, *baixi*白锡, *woyuan*倭铅/窩铅, and *woyuan baishuiyuan*倭源白水铅; however, it is difficult to unequivocally identify these terms due to their uncertain and changing meanings in different contexts. Based on historical records and limited analyses of coins, several views concerning the dates for the origins of zinc production in China have been put forward, including the Han Dynasty, the Five Dynasties, the Song Dynasty, and the early Ming Dynasty, but all were subsequently challenged. Since the 1980s, Zhou Weirong and his colleagues have reviewed all relevant textual evidence, offered new interpretations for some terminology and documents on which the previous discussions had been based, and carried out systematic analyses on copper-based coins. They argued that China did not begin to smelt zinc on a large scale before the Wanli period (AD 1573–1620) of the Ming Dynasty (Zhou 2007).

The earliest document clearly describing zinc distillation is *Tian Gong Kai Wu* 天工开物, which was written by Song Yingxing and published in 1637. It records that *woyuan* 倭铅 (zinc) was produced from *luganshi* 炉甘石 (oxidic zinc ores) in earthen jars, and it is described as a volatile metal. However, the text and illustration failed to show a method of distillation for the production of zinc. It is difficult to trace firm evidence of zinc production from Ming documents.

It was not until the discovery of nearly 20 zinc smelting sites dated to the Ming Dynasty (AD 1368–1644) along the Yangtze River in Fengdu, Chongqing, southwest China, since 2002 that allowed the first high resolution and contextualized technological reconstruction of zinc distillation. The analytical results of zinc ore, metal, retorts, and slag from three of these sites reveal the use of large-scale installations for zinc distillation with retorts made of pots, condensers, pockets, and lids. The retorts were charged with iron-rich oxidic zinc ores, coal, and charcoal; a high temperature of around 1,200 °C and highly reducing atmosphere were achieved to reduce the ores; the zinc vapor formed within the pots was cooled and collected in the condensers (Fig. 1). A few foundations of rectangular furnaces resembling the trough-shaped furnaces used in traditional zinc smelting were excavated. The retorts should have been placed on brick bars within the coal-fuelled furnaces (Fig. 2) (Liu et al. 2007; Zhou et al. 2012).

The picture of zinc production in Qing China is much better illustrated in historical texts. Several scholars studied the administration of zinc production and transport in southwest China based on Qing documents. During this period, zinc production was on a much larger scale in many provinces, such as Guizhou, Yunnan, Sichuan, Hunan, and Guangxi; Guizhou was the largest production area. Several zinc smelting sites of the Qing Dynasty were found 50 km southeast of Fengdu sites in Shizhu, Chongqing. The analytical results of production remains from one of these sites show that it employed a broadly similar technology to those at the Ming sites, but they used lower-grade oxidic zinc ores, a lower proportion of reducing agents, and elongated retorts

Zinc Production in China, Fig. 1 Reconstruction of a retort from zinc smelting sites in Fengdu (g gas, l liquid, s solid)

of inferior performance, leading to greater losses of zinc. The reasons for the lower technical efficiency at the later site are explained in terms of different social, political, and economic constraints (Zhou et al. 2014). In addition, zinc smelting sites were also found in Huanjiang, Guangxi (Huang et al. 2012), and Hezhang, Guizhou. The retorts at these sites are similar in shape to Dafengmen ones, suggesting that they were dated to the Qing Dynasty.

The traditional zinc smelting technology survived and evolved in southwest China throughout the twentieth century. They were in operation in Hunan province and the area where provinces of Sichuan, Guizhou, and Yunnan meet. Since the 1910s, a number of geologists, metallurgists, and historians of metallurgy have investigated these processes and left over ten ethnographic documents, which described the operational sequences from retort production, mining and ore preparation, reducing agents and fuel preparation, furnace construction, tool making, to zinc smelting. The traditional processes mainly used conical or

Zinc Production in China,

Fig. 2 Trough-shaped furnaces used in Guizhou, southwest China, in the 1980s

cylindrical retorts, while normally no extensions were added and zinc was collected in the pockets placed within the pots. Besides the rectangular trough-shaped furnaces, saddle furnaces and climbing hillside furnaces were also developed (Xu 1986; Craddock and Zhou 2003). As traditional zinc smelting processes caused serious harm to human health and pollution to the environment, they were forbidden by the Chinese government at the end of the twentieth century.

Zodiac in Indian Astronomy

Michio Yano
Faculty of Cultural Studies, Kyoto Sangyo
University, Kyoto, Japan

The signs of the zodiac originated in Mesopotamia. In the first stage of development, 12 constellations along the ecliptic (i.e., the apparent course

of the sun in the sky) were roughly marked out and each was named after the animal whose shape it resembled. Later, with the need for a rigid coordinate system for planetary positions, the zodiacal sign assumed a new meaning: the length of 30° along the ecliptic, so that 12 equal signs comprised a complete circuit (360°) of the ecliptic. The change from the older irregular constellations to the signs of regular spacing took place somewhere around 500 BCE.

In the cuneiform texts the ecliptic coordinates were sidereally fixed, and the vernal equinox was several degrees off “the first point of Aries”: at the tenth degree of Aries in System A and at the eighth in System B. The Mesopotamian idea of 12 zodiacal signs of equal length was transmitted to Greece about 300 BCE, where the iconography of the signs was modified by their mythology.

With the discovery of the precession of equinoxes by Hipparchus in about 150 BCE, the significance of the zodiacal signs changed drastically. The first point of Aries was equated with the vernal equinox. Since this is in constant retrograde motion relative to the fixed stars (the shift being about 51 min of arc per year), the original relation between the constellations and signs was completely severed and the zodiacal signs became a purely mathematical reference system.

With the development of astrology, which preserved the old association of zoomorphic shape with zodiacal signs (except Libra), the zodiacal signs assumed new meanings. They were classified in various ways: by sex, the ownership of the house of planets, seasons, tastes, four humors, four elements, the governorship over parts of the body, plants, animals, geographical regions, etc.

All these ideas were transmitted to India in the second century of the Christian era. The very Sanskrit names of the zodiacal signs show that they were translated from Greek. In some texts even phonetic translations of Greek words are found. The earliest Sanskrit text which contains a list of these names is the *Yavanajātaka* (ca. AD 269), a Sanskrit version of a Greek book on horoscopic astrology (Table 1).

Zodiac in Indian Astronomy, Table 1 The signs of the zodiac

Degrees	English	Sanskrit
0	Aries	<i>meṣa</i>
30	Taurus	<i>vṛṣan</i>
60	Gemini	<i>mithuna</i>
90	Cancer	<i>karkāṭa</i>
120	Leo	<i>siṃha</i>
150	Virgo	<i>kanyā</i>
180	Libra	<i>tulā</i>
210	Scorpio	<i>vṛścika</i>
240	Sagittarius	<i>dhanus</i> or <i>dhanvin</i>
270	Capricorn	<i>makara</i> or <i>mṛga</i>
300	Aquarius	<i>kumbha</i>
330	Pisces	<i>mīna</i>

Three iconographic modifications in the process of transmission are worth mentioning. (1) While Gemini are the twin boys in Western iconography, *mithuna* in Sanskrit is a couple consisting of a male and a female, and this was interpreted as “husband and wife” in Chinese texts on Buddhist astrology. (2) The Sanskrit word *makara* stands for a kind of sea monster, and *mṛga* for a “forest animal” such as a deer. Thus Capricorn was divided into two separate animals. (3) The word *dhanvin* (one who has a bow) is a better translation of Sagittarius (archer), but the simpler *dhanus* (bow) without a human figure is more frequently used in Sanskrit texts.

In spite of the similarity of the names, the astronomical meaning of Indian zodiacal signs is different from that of the Western ones, because the precession of the equinoxes was not taken into account in India, and the first point (*meṣādi*) of the ecliptic coordinates was sidereally fixed sometime in the third or fourth century AD. The difference (*ayanāṃśa*) between the vernal equinox and the *meṣādi*, which has accumulated in the present day, is about $23^\circ 40'$; thus the sun’s entry into *meṣa* now falls on the 14th of April, and the *makarasaṃkrānti*, originally a winter solstice festival, on the 15th of January.

This seemingly conservative attitude is closely related to the Indian system of naming the lunar month. A year is divided into 12 solar

months by the sun's entry (*saṃkrānti*) into a new zodiacal sign. The lunar month is named after the *saṃkrānti* which falls during that month. For example, the lunar month Caitra is defined as the month during which the sun's entry into *meṣa* occurs. The full moon of that month has to be located near the diametrically opposite point on the ecliptic, i.e., at the lunar mansion *citrā*. Thus, in order to keep the relation of the month name and the constellation name, they had to stick to the sidereal (*nirayana*) system even at the sacrifice of the correspondence between the seasons and month names.

The Western system has ignored the original association between constellations and zodiacal signs, and the word *Aries*, for example, has two meanings, one as an actual constellation and the other as the first 30° in the ecliptic longitude. The former is used in astronomy and the latter in astrology. This is not the case in the traditional Indian system.

In South India and Nepal the solar month is still used in the civil calendar. Since a solar month is the time during which the true sun stays in one zodiacal sign, the length of a month varies from 28 to 32 days.

As mentioned above, Indian zodiacal signs were transmitted to China in the eighth century by Buddhist astrology and ultimately to Japan in the ninth century. The iconography of the Indian zodiacal signs was preserved in the star *maṇḍalas* (especially in the temples belonging to the Shingon sect) which were used in the ritual of worshipping the planetary deities.

Zodiac in Islam

Paul Kunitzsch

University of Munich, Munich, Germany

The zodiac, i.e., the band or zone around the sky through which the sun, the moon, and the planets travel in their apparent revolutions, was first established by the Babylonians. They formed the constellations along this zone and instituted its division into 12 equal portions, the “signs.” This knowledge was then handed on, in a northern branch of transmission, to the Greeks and through them further on into modern astronomy. In a southern branch of transmission, some of the zodiacal constellations reached the Arabs in the Arabian peninsula. In their folk astronomy they knew some of the zodiacal constellations – though not the complete system of 12 – which, in their astronomical lore, were sometimes located differently. For example the constellation *al-jawzāʾ* (standing for Gemini) is located in the Greek (and modern) Orion, *al-dalw* (Aquarius) in Pegasus, and *al-ḥūt* (Pisces) in Andromeda.

With the reception of Greek astronomy, through the translation of the most important Greek writings in astronomy and astrology, the system of the 12 zodiacal constellations and the 12 signs was also received and continued to be used by Arabic-Islamic astronomers and astrologers. For some constellations the translators introduced new names (derived from Greek) besides the names inherited from the old Arabs. The names for the 12 constellations of the zodiac in Arabic are:

1. Aries: *al-ḥamal*
2. Taurus: *al-thawr*
3. Gemini: *al-jawzāʾ* (old), *al-tawʾamān* (transl.)
4. Cancer: *al-saraṭān*
5. Leo: *al-asad* (both old and transl.)
6. Virgo: *al-sunbula* (old), *al-ʿadhraʾ* (transl.)
7. Libra: *al-mīzān*
8. Scorpio: *al-ʿaqrab* (both old and transl.)
9. Sagittarius: *al-qaws* (old), *al-rāmī* (transl.)

10. Capricornus: *al-jady*
11. Aquarius: *al-dalw* (old), *sākib al-mā'* (transl.)
12. Pisces: *al-ḥūt* (old), *al-samakātān* (transl.)

The zodiac was treated by the Arabic-Islamic astronomers and astrologers according to the teachings of the Greeks. When Arabic astronomical and astrological works were translated into Latin in Europe in the Middle Ages, the Arabic names of the 12 zodiacal constellations were also sometimes borrowed. But they did not gain the same popularity as the Arabic star names and the names of the lunar mansions; most Latin authors used the well-known Latin names for them.

Zou Yan

Christopher Cullen
Needham Research Institute, Cambridge, UK

Our only source on Zou's life that has any chance of being reliable is the entry in Sima Qian's universal history *Shiji*, completed ca. 90 B.C.E. According to this, Zou (fl. 250 B.C.E.) was a successful member of the group of wandering scholars who moved from one feudal court to another in China's Warring States period (fifth-third centuries B.C.E.), offering expertise in statecraft and useful arts. He came from the northeastern seaboard state of Qi, where he became a member of the "academy" set up by the ruler of that state to house his more favored scholarly retainers. Although he is said to have written several voluminous books none of them has survived.

According to the *Shiji*, Zou "looked into the rise and fall of the Yin and Yang" and wrote on

their "strange transformations." His method of reasoning "started by checking some small thing, and then extrapolated to a large scale." On this basis he is said to have reasoned his way back to the state of affairs "before the origin of heaven and earth" on the basis of his knowledge of more recent times. Similarly, he claimed that China only occupied one-ninth of a large continent, which was itself only one out of nine giant land masses surrounded by a vast ocean.

One source of the seventh century A.D. (Li Shan's commentary on the Wen Xuan anthology) quotes a work said to be by Zou Yan, in which it is stated that he taught that the successive dynasties ruling in China had each come to power by virtue of the cyclical dominance in the cosmos of one of the *wude* (Five Powers) of earth, wood, metal, fire, and water. (These are more commonly called the wuxing, Five Phases.) While such a view is not inconsistent with Zou Yan's thought as known from the *Shiji*, it is by no means certain that he originated it. Whatever its origins, this theory of the cosmological determination of political dominance was adopted by the first emperor of the Qin dynasty when he came to the throne in 221 B.C.E., and remained important for several centuries thereafter.

Zu Chongzhi

Ang Tian Se

Zu Chongzhi, whose literary name was Wenyan, was born in Jiankang (present ► [Nanjing](#) of Jiangsu Province) in AD 429 into a family of bureaucrats. His great grandfather, a native of Hebei Province, was an official during the

Eastern Jin dynasty (AD 317–420), and his grandfather and father were officials of the Northern and Southern dynasties (AD 479–581). Interestingly enough, the Zu family had, for successive generations, been involved in studies of astronomy and calendrical science. Subsequently, they moved south and settled in Jiankang, the political and economic center of the fifth and sixth centuries. From a very young age, Zu Chongzhi received instruction in a variety of subjects. He was particularly interested in mathematical astronomy. While examining many past and existing astronomical systems, he found many errors and discrepancies. This prompted him to compile a calendrical system known as the Daming calendar (Calendar of Great Brightness). However, when he presented this calendar to the throne for promulgation in AD 462, he met with vehement opposition from the emperor's minister Dai Faxin. Zu Chongzhi's innovation and improvement in the astronomical system was branded as "distorting the truth about heaven and violating the teaching of the classics." The Daming calendar was shelved for about half a century before it was finally promulgated for official use in AD 510 when Zu Chongzhi had been dead for 10 years.

The Daming calendar was the epitome of Zu Chongzhi's mathematical and astronomical skills. He was the first person to take into account the fact of precession of the equinoxes discovered by Yu Xi, an astronomer in the fourth century AD. By applying the precession of equinoxes, Zu Chongzhi differentiated the tropical year from the sidereal year (the time at which the sun's center, departing eastward from the ecliptic meridian of a given star, returns to that meridian). As a matter of fact, he determined several astronomical constants with remarkable accuracy. For example, he gave a value of 365.24281481 days for the tropical year, only about 50 s off the modern value. He also gave a value of 27.21233 days for the length of a nodal month, the modern value being 27.21222 days. For planetary motion, he found that the planet Jupiter completes 7 and 1/12 circuits of the heavens in every 7 cycles of 12 years. This gives Jupiter a sidereal period of 11.859 years, which differs from the modern value by only 1 part in 4,000.

In order to make the lunar year tally with the solar year, ancient Chinese calendar makers inserted 7 intercalary months in every 19 years. This rule of intercalation had been in use for more than a thousand years until AD 412 when Zhao Fei changed it to 221 intercalary months in every 600 years. Zu Chongzhi did not find the rule satisfactory and improved it by introducing 144 intercalations in every 391 years.

The most significant contribution by Zu Chongzhi is in the evaluation of π . He gave two approximating ratios for π : a coarse 1 of 22/7 and a fine 1 of 355/113. The true ratio, according to him, lies between 3.1415926 and 3.1415927.

Zu Chongzhi also wrote a mathematical text known by the title *Zhui Shu*. This text, prescribed as a textbook for advanced students of mathematics in the official examinations of the Tang dynasty, was unfortunately lost in the wars of the early twelfth century. Only fragments of the text still exist in the Calendrical and Astronomical Chapters of the Sui and Tang dynasties. Zu Chongzhi was said to have worked out an evaluation of the volume of a sphere. He considered a sphere as a pile of circles of varying sizes and arrived at a formula, which in modern mathematical language, could be expressed as $V = 4/3\pi r^3$.

Zu Chongzhi was a versatile person. Apart from being a celebrated astronomer and mathematician, he was well versed in engineering. He produced a "south-pointing vehicle" worked by a set of five differential cog wheels, a "thousand-mile boat" propelled by paddle wheels, a hydraulic mortar-mill, worked by a combination of separate water-driven mortars and mills, and a brass ruler for measuring the pitch of musical instruments.

Zu Chongzhi's remarkable achievements are acknowledged internationally. A crater on the reverse side of the moon, just south of the Sea of Moscow, is named after him.
